

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

LABORATORIES**

# Making voices from the depths sound deeper

Bell Telephone Laboratories has had a long-term interest in speech research—tracing back, indeed, to the work of Alexander Graham Bell. It was for this reason that the U. S. Navy asked us to investigate a

problem encountered in Sealab II. To prevent "bends" and nitrogen narcosis, the divers breathe a pressurized mixture of oxygen, nitrogen and helium, but the helium gives their voices an unnatural,

squeaky, Donald-Duck-like quality. As a result, voice communication between divers and people on surface are seriously impaired.

THE MAJOR PROBLEM is that the velocity of sound in the helium mixture is much higher than in air. This does not appreciably affect the vocal-cord frequency, but it strongly affects the acoustic resonances of the vocal tract—which give the voice its characteristic sound quality. So, though fundamental voice pitch remains approximately the same (about 100 Hz in men), the amplitude loudness values of the various harmonics change markedly. Specifically, the pattern of these resonances (the envelope shown in the graph), and voice timbre is greatly distorted.

THE SOLUTION to this problem was found at Bell Laboratories by research scientists M. R. Schroeder, J. L. Flanagan, and R. M. Golub. The distorted "helium speech" is separated into harmonic frequencies and their amplitudes are measured (see diagram). Then the envelope of the harmonic amplitudes is shifted back toward more normal or low-frequency condition. In other words, amplitudes of the harmonics are adjusted to match a more normal envelope.

As a test, the technique has been used on recordings of helium speech made in the U. S. Navy Sealab II. The processed voice is readily understandable and sounds enough like the speaker's original voice to be identifiable.

## DISAPPOINTED IN D.T.A.? TRY THE NEW PERKIN-ELMER DSC-1B!

How would you like to have a thermal analysis instrument that gives you all these—

- Direct, simultaneous, quantitative measurement of ordinate displacements as specific heat... of peak areas as energy of transition.
- The fastest controlled heating and cooling rates. Heat to and equilibrate at any temperature to 500°C in less than a minute. Run down to and up from -100°C without elaborate, troublesome coolant systems.
- Operate in vacuum or any desired atmosphere with optimum atmosphere-sample contact and exchange.
- Versatile operation—doesn't need costly accessory units.
- Built-in thermal conductivity effluent detector, linear temperature and time-base recorder, analyzer assembly separate from control unit. Observe the sample while running.
- Sample easily encapsulated in a metal pan... removable at any time to observe weight changes. Pressure sealer for volatile samples.
- Unsurpassed temperature precision, resolution, sensitivity, sampling ease and baseline stability.

If you're thinking that no Differential Thermal Analyzer can possibly meet this description at any price—you're right. We call ours a **Differential Scanning Calorimeter**.<sup>\*</sup> It's the only thermal analyzer that takes advantage of modern electronic developments to give the chemist the answers he really wants. It's the lowest-cost

<sup>\*</sup>Patent applied for

high-performance thermal analysis system commercially available.

Who needs it? You do—if you want to determine purity and heat of fusion of crystalline organic compounds in the same time you now take for a simple melting point—to measure temperature, heat, rate, effluent gases and weight change of a reaction in a single experiment—to analyze quantitatively multi-component solid mixtures such as fiber blends—to determine reliable  $\Delta H$  values for phase changes—even for low-energy liquid-crystal transitions and protein denaturation.

Detailed information on purity is in Thermal Analysis Newsletter No. 5. Heat capacity is in Newsletter No. 3. Write for these two informative reports today to Instrument Group, Perkin-Elmer Corporation, 720 Main Avenue, Norwalk, Conn. 06852.

### Business and Subscription Information

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the Subscription Service Department, American Chemical Society, 1155 Sixteenth Street, N.W., Washington, D. C. 20036. Change of address notification should include both old and new addresses, with ZIP codes, and a mailing label from a recent issue. Allow four weeks for changes of address.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue plus time normally required for postal delivery of journal and claim, (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Subscription rates for 1967: to members, \$16.00 per year, to nonmembers, \$32.00 per year. Postage to Canada and countries in the Pan-American Union, \$2.50; all other countries, \$3.50. Back volumes: Vol. 36-88, \$48.00 per volume; foreign postage, per volume, \$3.50; to Canada and countries in the Pan-American Union, \$2.50.

Single copies: back issues, \$2.50; for current year, \$2.00; postage, single copies: foreign, \$0.20; Canada and Pan-American Union, \$0.15.

*Notice to Authors printed on pages 19A and 20A of this issue*

## Everything from A to X

Volk's in-stock C-14 organic research compounds go from Acetaldehyde-1, 2-C-14 to Xylose-1-C-14.

In between, we offer over 2000 isotopic chemicals, most available for *immediate delivery*. Each labeled compound is *warranted* to meet stated standards of purity—one reason why, for fifteen

years, research people have relied on Volk as the trusted radioisotopic supplier.

You can read all about our *extensive C-14 inventory* (and the prompt way we process your order) in our new catalog No. 7. Write for your free copy today

From A to X, you will learn the entire Volk alpha

## MASS SPECTROMETRY OF ORGANIC COMPOUNDS

By HERBERT BUDZIKIEWICZ, Technische Hochschule Braunschweig; CARL DJERASSI, Stanford University; and DUDLEY H. WILLIAMS, Cambridge University

"Interpretation of Mass Spectra of Organic Compounds" by the same authors was published in 1964 and immediately became one of the most popular and widely quoted texts in the field. The explosive growth of the subject matter in only three years has required three-fold expansion of the subject matter as well as virtually complete rewriting of the earlier material. For this reason the new book bears a different title, since it is not just a revised edition of the 1964 pioneering text. The present volume of over 700 pages covers in 27 chapters the fragmentation behavior of all the important functional groups in organic chemistry. In addition, a summarizing chapter has been included which greatly aids in the interpretation of mass spectra of organic molecules. The literature is complete through early 1967, and the book should prove to be indispensable as a text in organic chemistry courses as well as a guide for the expert and novice alike who wish to become familiar with the numerous organic chemical applications of mass spectrometry.

**CONTENTS:** Introduction. Hydrocarbons. Alcohols. Aldehydes and Ketones. Esters and Lactones. Acids and Anhydrides. Ethers, Acetals, Ketals and Orthoesters. Thiols, Thioethers and Related Compounds. Amines, N-Oxides, Nitrosamines and Quaternary Ammonium Salts. Amides and Lactams. Nitrogen-Containing Carbonyl Derivatives. Cyanides and Related Compounds. Halides. Epoxides. Alcohol Derivatives. Carbonates, Carbamates, Ureas and Thio Analogs. Nitro and Related Compounds. Quinones. Tropones and Tropolones. Sulfoxides, Sulfones and Related Compounds. Pyridines, Quinolines and Isoquinolines. Pyrazines, Pyrimidines and Related Heterocyclics. Pyrroles and Indoles. Furans and Related Compounds. Thiophenes and Benzothienophenes. Thiazoles, Oxazoles, Oxadiazoles, Imidazoles and Pyrazoles. Organic Phosphorus Compounds. Organometallic Compounds.

## Micro-mesh sieve sets 90 to 20 microns, measure particle size

Buckbee Mears sieves, made by an entirely new process, have established a new standard of measurement in the control of sub-micron particles. Sieves in standard three inch sets in 90, 75, 60, 45, 30 and 20 micron hole sizes, with guaranteed accuracy to  $\pm$  two microns, are available from stock. Sizes down to five micron openings and up to eight inch diameters are made to order.

# Mathematics for Scientists

Vectors, Tensors, and Groups  
Volume I

Functions of One and Several Variables  
Volume II

Series, Differential Equations,  
and Complex Functions  
Volume III

**Thor A. Bak**  
University of Copenhagen

**Jonas Lichtenberg**  
Royal Danish College of Education

Three Volumes  
Each \$2.95/\$2.36 prepaid\*

Originally published in a one-volume cloth edition, this important supplement is now available (for greater flexibility) as three paperbacks. The three volumes, which can be used independently of each other, strengthen mathematical understanding and ability so that mathematics can be used as a readily available tool for solving scientific problems.

## CONTENTS

### Vectors, Tensors, and Groups, Volume I

1. Vectors and Tensors
2. Groups and Group Representations

### Functions of One and Several Variables, Volume II

3. Functions of One Variable
4. Functions of Several Variables

### Series, Differential Equations, and Complex Functions, Volume III

5. Infinite Series
6. Differential Equations
7. Complex Functions
8. Numerical Analysis

## BEILSTEIN'S HANDBUCH DER ORGANISCHEN CHEMIE

**Friedrich Konrad Beilstein**  
**4 Auflage, Berlin, Springer, 1918-44**  
**64 vols. in 53**

Main series, vols. 1-27, 30-31, pt. 1. First supplement, vols. 1-27. Subject and formula indexes to vols. 1-27 of main series and first supplement, vols. 28-29 in 4 pts. Second supplement, vols. 1-6.

This work has been published by J. W. Edwards, Publisher, Inc., since 1943 by authority of the now-disbanded Office of Alien Property Custodian, Department of Justice. These 175 sets are the last to be sold under their auspices at this advantageous price.

**Entire 64 vols. in 53 \$850.00**

**J. W. EDWARDS, PUBLISHER, INC.**  
Ann Arbor, Michigan, U.S.A.

## Natural Pest Control Agents

### ADVANCES IN CHEMISTRY SERIES NO. 53

*Surveys agents produced by plants and animals which can control life processes in insects or in other plants:*

- insect attractants
- repellants in arthropods
- insecticides in pyrethrum, in turnips, and in cruciferous crops
- insect toxicants in crystalliferous bacteria
- biologically active agents in fungi
- antifungal factors in barley
- virus inhibitors and stimulators in plants
- abscission-accelerating hormones in cotton fruit
- growth regulators in higher plants

146 pages with index cloth bound (1966) \$5.75 postpaid in U.S. and Canada; plus 20 cents foreign and PUAS.

Set of L.C. cards free with library orders.

## Chemical Titles Tapes & Search Services

*Does your present information program provide:*

- Computer scanning of titles of papers published in 725 of the most important domestic and foreign chemical and chemical engineering journals each month, often in advance of publication of the journal itself?
- An indexing service for many of the journals in your library?
- Screening of titles of papers by computers to give you only the information which you need to answer specific requests?
- Searching of the chemical literature by computers rather than manually?

You can add these services to your information program through use of the computer tapes generated in the preparation of *Chemical Titles* — a biweekly alerting publication.

You decide the terms which are to be used as search questions and the form in which you want the answers to your search questions — journal references, author indexes, keyword indexes, or any combination of the three.

The tapes may be searched either on your computers or at

the Chemical Abstracts Service. A subscription provides for searching of 26 tapes each year. If you do not feel that your needs warrant a yearly subscription, you can request searches of any portion of the CT tape file whenever you need them and pay only for the searches which you request.

No matter how you choose to use the tapes and searches you are covering a large portion of the important chemical literature at a low unit cost.

*For subscription information, contact the Service Division, Chemical Abstracts Service, Box 1378, Columbus, Ohio 43216 (telephone 614 293-5022).*

# Imagine . . . an all-purpose mass spectrometer with complete data handling.

## Congratulations! You've just dreamed up the 21-110B.

Without a doubt, this is the most advanced mass spectrometer in the world today.

With it, researchers (such as organic chemists) are given absolute answers for compound identification and structural elucidation. So efficient is this system, it is used in more laboratories than all other high resolution instruments combined.

To facilitate the full, economic use of mass spectrometer output, CEC, the recognized leader in both mass spectrometry and data handling, offers a complete and proven line of equipment for automated and computer data processing. Such as:

**The 21-087 Automated Mass Spectrum Data System** which scans photoplate records produced by the 21-110B, the instrument producing the highest precision mass measurement available. Automatically entered on digital magnetic tape are the location and density of each spectrum line.

**The APR-1 Automatic Plate Reader** which is somewhat comparable to the 21-087, except that incrementing between spectra is manual.

**The Ion Density Computer** which is used in conjunction with photographic plate spectra from a spark-source 21-110B Mass Spectrometer, or similar photoplate record. The computer greatly reduces the time factor, and is far more accurate than manual methods of reducing plate transmission of spectral lines to concentration.

**Direct Digital Recording.** Direct digital recording of the analog signal permits rapid sampling (every 30 microseconds) of the resolved ion beam signal and subsequent digitization of the data.

**FM Magnetic Tape.** In this alternate system, the resolved ion beam analog signal is recorded directly onto FM magnetic tape. This taped data can be used as an input to a recording oscilloscope or digitized and fed directly into a computer for processing.

**Direct Computer Link-Up.** In the most sophisticated method of automatic data acquisition, the analog signal from the mass spectrometer is accepted, digitized and processed directly by the computer on a real-time basis.

Those are some of the reasons: CEC is the recognized leader in mass spectrometry and data handling. And why CEC is the *only* source of the associated equipment required today's technology.

For complete information, call nearest CEC Field Office. Or Consolidated Electrodynamics, Inc., Pasadena, California 91109. A subsidiary of Bell & Howell. Bulletin Kit #32

# NOTICE TO AUTHORS OF PAPERS

The *Journal of the American Chemical Society* is devoted to the publication of research and will consider contributions which have not been and are not to be published elsewhere. Articles, Communications to the Editor, and Book Reviews are published, the latter prepared by invitation of the editor.

**Articles.** Manuscripts of articles to be considered for publication in the *Journal of the American Chemical Society* may deal with any phase of "pure" or "fundamental" chemistry as distinguished from "applied" chemistry. The number of pages budgeted per year for the *Journal of the American Chemical Society* is fixed, and an increase is not planned. Since the *Journal of the American Chemical Society* covers all phases of "pure" or "fundamental" chemistry, special attention will be given to articles of general interest.

**Communications to the Editor.** Communications to the Editor are preliminary reports of unusual urgency, significance, and interest. The total length is limited to 1000 words. An average-sized figure is counted as 80 words; separate formulas and lines of a table are counted as 8 words per line including headings and horizontal rulings. Literature references in footnotes, title, and authors' names are not counted. Other footnotes are counted as text. Communications to the Editor differ from articles in that the subject matter may be republished. Communications will not be accepted if, in the opinion of the editors, the principal content has received prior publication or publicity in any other published medium. They will be handled as expeditiously as possible and may not always be sent to referees. Additional supporting information may be requested even if space limitations will not permit its publication. Although Communications to the Editor are given expedited publication, proof will be sent, and its return awaited, unless the author has specifically approved printing without opportunity to correct proof.

**General Considerations.** Authors should present their materials with the utmost conciseness consistent with clarity. Extensive reviews of the literature cannot be accepted. Well-known procedures either should be designated by name or literature references to them should be given. Footnotes acknowledging financial assistance to the conduct of the research, citing theses, or indicating presentation at a meeting should be brief and preferably combined under one number. A footnote giving the name and address of the author to whom inquiries should be addressed may be included, but addresses and titles or connections of authors should not be given. Introductions should contain only enough background material to show why the work was done. Experimental results if carefully obtained are of lasting value and should be clearly and logically presented in separate sections. Results and discussions should not be intermingled.

Abstracts must state the reason for the work, the significant data, and conclusions. The requirements for a good abstract are not necessarily the same as for *Chemical Abstracts*, but by a recent policy change *Chemical Abstracts* now makes direct use of many of our abstracts with such editing and revising as may be required; abstracts cannot, of course, mention all new compounds and their properties.

Articles should be classified by the authors as (a) Inorganic, (b) Physical, (c) Organic, or (d) Biological.

The editors will welcome suggestions from authors as to persons competent to referee manuscripts.

**Functions of Referees.** The editors seek the advice of experts about manuscripts. The recommendations of referees may not always be followed by the editors, who accept full responsibility for decisions about manuscripts. Referees should give estimates of the scientific value of the work together, if possible, with some basis for their opinion. They should indicate whether the writing is clear and concise. Improperly used space merely restricts the amount of useful materials which can be published.

Articles which describe good scientific work cannot always be accepted by the *Journal of the American Chemical Society* because of restrictions on its size. Referees should realize that their reports may be transmitted by the authors to the editors of other journals. Thus, articles upon which referees have commented favorably may be returned to the authors with the referees' reports and with the

statement that, if they so desire, they may send the unchanged manuscript and the referees' reports without delay to editors of other journals of the American Chemical Society, who may request the identity of the referees from the editors of the *Journal of the American Chemical Society*. The names of referees will not be given without their consent to authors of papers they have refereed. Articles reported upon unfavorably by referees will be returned to authors, and there will be no communication about them with the editors of other journals.

**General Instructions.** Manuscripts must be submitted in duplicate, but more expeditious action is possible if three copies are supplied. They should be typewritten double-spaced, preferably on 8.5 × 11 in. paper, and one copy must be good, clear typescript, stencil- or photoduplicating machine product. All pages of a manuscript should be numbered consecutively, including tables, which should be inserted in their proper places rather than grouped at the end. The original manuscript should include the engraver's copies (see later) of graphs and drawings of apparatus; these should be placed at the end, but authors should indicate by text or marginal notations in the typescript where the figures are to be inserted. The diagrams with duplicate copies may be photoprints or rough drawings.

The attention of contributors is directed particularly to the requirement that all nomenclature should be consistent, clear, and unambiguous, and conform to the usages of *Chemical Abstracts* and the conventions recommended by the International Union of Pure and Applied Chemistry, when feasible. When in doubt, writers should consult the indexes of *Chemical Abstracts*; "The Naming and Indexing of Chemical Compounds" (introduction to the *Chemical Abstracts* Subject Index, Vol. 56, 1962); the "Ring Index," A. M. Patterson, L. T. Capell, and D. F. Walker, Second Edition, Special Issues Sales Department, American Chemical Society, Washington, D. C. 20036, 1960; the various reports and pamphlets of the American Chemical Society Committee on Nomenclature, Spelling, and Pronunciation; and the IUPAC Reports on Symbolism and Nomenclature of Physical, Inorganic, Organic, and Biochemistry, *J. Am. Chem. Soc.*, 82, 5517 (1960), available from The Chemical Abstracts Service, The Ohio State University, Columbus, Ohio 43210. Rigid and consistent conformance to these rules throughout a manuscript is not required, but the approved names of compounds should be given at least once (in parentheses or in footnotes) and in proper relation to the compound name. The use of code or letter designations for compounds is not encouraged and should be minimized. Infrared and ultraviolet spectra will be accepted for full presentation if they accompany a comprehensive study of such spectra leading to significant theoretical or practical conclusions, if such full presentation is necessary to establish definite results or conclusions, if the spectra themselves show abnormalities or features of great interest, or if the compounds are inherently of special interest or importance. They will not be accepted merely as adjuncts to characterization of compounds.

When X-ray powder measurements are reported but the actual X-ray data are not given, it is suggested that the data be submitted to J. V. Smith, Editor, "A.S.T.M. X-Ray Powder Data File," Department of Geology, University of Chicago, Chicago, Ill. 60637. The data should include accurate listings of  $d$  values, intensities of reflections,  $hkl$  indices, lattice parameters, radiation used, type of X-ray recording, method of estimating intensities, and relevant information on the specimens used.

It will be of great assistance to the Editor's office if the style, arrangement, and orthography of the manuscripts are made to conform to the new usages of the *Journal* as exemplified in recent issues, and the typescript is prepared in form and style identical with that of printed papers. In the main heading of an article, the address of the contributing authors and laboratory should be complete with city and state; the title should be as briefly informative as possible and should not contain formulas or other symbols. Subheadings should be employed sparingly; side headings should be paragraph indented and run into the following text with a period. Registered trademark names should be capitalized whenever used; trade and trivial names should not be

capitalized; usually the chemical name or composition should be given in parentheses or in a footnote at the first occurrence of such a name. Metric system units should be used for all quantities of length, area, and volume.

**References, Abbreviations, etc.** *References* to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using the superscript number corresponding to the original reference. Reference numbers in the text should be typed as unparenthesized superscripts, but enclosed in parentheses in the footnotes, which may be placed at the bottom of the page or follow immediately in separate lines the line of text containing the words to which they refer, or be collected all on one page in proper numerical order (with first appearance in the text clearly marked in the margin; if this is not done, the manuscript will be returned for correction). Bibliographic references to classified documents and reports or to unpublished material not generally available to the scientific public should not be used. Literature references should be arranged and punctuated as shown:

(1) J. S. Doe, J. Smith, and P. Roe, *Am. Chem. J.*, **50**, 1234 (1913), thus including initials of authors and the journal abbreviation as proved by *Chemical Abstracts* in its "List of Periodicals Abstracted." Citations to the *Journal of the American Chemical Society* should use the form *J. Am. Chem. Soc.*, rather than *THIS JOURNAL* (as formerly used); this change has been made so that manuscripts may be transferred easily from one journal to another.

**References** to books should include author, title, volume, publisher, address, date of publication, and pages, thus:

(2) A. B. Smith, "Textbook of Organic Chemistry," Vol. 1, D. C. Jones and Co., New York, N. Y., 1961, pp 123-126.

Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the usual manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). These frequently occurring abbreviations are preferred: %, °K, cm, ml, l, g, mp, fp, bp, cal, kcal, kX, ac, dc, v, mv, amp, ev, emf, nmr, epr, no., A, hr, min, sec, cps, ppm, and eq.

**Tables.** Tables should be used only in case they will present information more effectively than running text. If reasonably possible, they should be designed to occupy fully a single column (3¼ in.), which will take 50-75 characters and spaces, or the full width of a page, which will take 110 to 150. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and the column heads should be made as brief as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text and need not be placed alone on separate sheets.

**Figures and graphs** should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth, or coordinate paper printed in blue only. The originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are more conveniently handled when made in the conventional 8.5 × 11 in. manuscript size; if they are of necessity larger and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size also should be furnished. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes during subsequent handling by the editors, printer, and photoengraver). Diagrams should be designed tall for single column or wide for double column size. With this principle in mind particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and any letters, numbers, or legends which must be placed on the diagram. In graphs the frame and actual curves should be ruled and inked more heavily than the coordinate lines. Experimental points usually should be given and be indicated by

circles or other simple symbols carefully drawn with instruments. Numbers or lettering on curves should be stenciled and inked in. If axis ordinate and abscissa numbers and units are carefully planned, punctuated, lettered, and inked, they will be included on the plate; otherwise this material will be typeset. Before any photoproduced cut copy is submitted, it should be examined carefully for broken lines, imperfect letters, poorly focused edges, and fogged areas, and such pieces repaired or remade; negatives, blueprints, and quick-process photoprints cannot be used by the engraver. Black background photos should be "reversed" when possible. Small drawings and prints should be mounted on heavy paper, and composite diagrams or photoprints likewise, in the desired order and in space-economical arrangement. Figures should be numbered in series and the caption, if short, placed below the diagram (never on it), or all such legends may be typed together on one or more separate sheets.

**Formulas and Equations.** Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single or double column. Subscripts and especially superscripts should be written with care and exponents should be set up in a single line, as  $e^{-90/RT}$ . All signs such as + - × = > < should be spaced, but the components of mathematical products should not be spaced. Organic structural formulas should be planned to fill space economically, using bonds and arrows vertically, horizontally, or at 45° angles, whenever possible. Since a large proportion of this material now is reproduced with plates from ruled and type-lettered cut copy, it is important in avoiding errors that all formula matter be carefully arranged and executed (preferably typewritten), with special attention to correctness of symbols, location of subscripts, superscripts, and electric charges, and the placing and close join-up of single and multiple bond lines. Phenyl groups should be shown as C<sub>6</sub>H<sub>5</sub> or Ph, not as φ. Small numbers showing ring positions should be placed outside rings, and if electric charges are shown + and - are preferred rather than ⊕ and ⊖.

**Microfilm and Photoprint Supplements.** By arrangement with the American Documentation Institute, % Library of Congress, Washington, D. C. 20540, supplementary material, such as extensive tables, graphs, spectra, and calculations, can be distributed in the form of microfilms with images 25 mm high on standard 35-mm film or as 6 × 8 in. photoprints readable without optical aid. Such material, having been submitted to and approved by the Editor, will be returned to the author with instructions for transmission to the American Documentation Institute accompanied by the \$2.00 deposit fee. When accepted by the Institute, each document is assigned a serial number, and the printed paper will have a footnote giving the serial number and the prices.

**Proofs and Reprints.** Galley proofs, original manuscript, cut copy, and reprint order form are sent by the printer directly to the author who submitted the article. The attention of authors is directed to the instructions which accompany the proof, especially the requirement that all corrections, revisions, and additions be entered on the proof and not on the manuscript. Proofs should be checked against the manuscript (in particular all tables, equations, and formulas, as this is not done by the editor) and returned as soon as possible, but no paper is released for printing until the author's proof has been received. *Alterations in an article after it has been set in type are made at the author's expense*, and it is understood that by entering such alterations on proofs the author agrees to defray the cost thereof. The filled-out reprint form must be returned with the proof. Confirming or purchasing office forms should be attached to the proof, and if a quotation is required a request for it should accompany the proof. Reprinting often is done from the journal press forms, so all orders must be filed before press time and none can be accepted later (unless previous request has been made to hold the type). Reprint shipments are made a month or more after publication, and bills are issued by the printer subsequent to shipment. Neither the editors nor the Washington Office keep any supply of reprints; requests for single copies of papers should be addressed to the author of the paper concerned.

A page charge is assessed to cover in part the cost of publication. Payment is expected but is not a condition for publication since articles are accepted or rejected only on the basis of merit, and the editor's decision to publish the paper is made before the charge is assessed. The charge per page is \$35.

### Microwave Absorption and Molecular Structure in Liquids. LXIX. Atomic Polarization and Relaxation in Several Siloxanes and Hexamethyldisilazane<sup>1</sup>

S. Dasgupta, S. K. Garg, and C. P. Smyth

*Contribution from the Frick Chemical Laboratory, Princeton University, Princeton, New Jersey. Received January 3, 1967*

**Abstract:** The dielectric constants and losses of hexamethyldisiloxane, hexaethyldisiloxane, hexamethylcyclotrisiloxane, octamethylcyclotetrasiloxane, and hexamethyldisilazane have been measured over a range of temperature at 2.2 mm wavelength and at centimeter wavelengths. The data have been used to calculate the dielectric relaxation times, the atomic polarizations, and the dipole moments. Use of the very large values found for the atomic polarizations in the calculation of the dipole moments gives much smaller moment values than those previously reported in the literature which did not take account of the atomic polarization. The large atomic polarizations and the short relaxation times found are consistent with the great flexibility which has been ascribed to the Si-O-Si bonds. They are discussed in terms of the structures of the molecules.

An anomalously low value for the dielectric relaxation time of hexamethyldisiloxane obtained from centimeter wavelength measurements<sup>2</sup> indicated the desirability of higher frequency measurements to establish the low value more exactly. The unexpectedly small dipole moment,<sup>2,3</sup> the large atomic polarization,<sup>2,3</sup> the wide Si-O-Si valence angle,<sup>4</sup> and the frequency of occurrence of the silicon-oxygen bond give additional reasons for the extension of the measurements to 2.2 mm wavelength. Four other silicon compounds have also been measured in the hope of throwing additional light upon the problems involved.

#### Measurements and Calculations

Hexamethyldisiloxane, hexamethyldisilazane, hexamethylcyclotrisiloxane, and octamethylcyclotetrasiloxane were obtained from the General Electric Co. in

very pure form. Hexaethyldisiloxane of similar purity (99.5%) was obtained from the Dow-Corning Corp. Measurements of dielectric constant  $\epsilon'$  and loss  $\epsilon''$  were made at wavelengths of 0.22, 1.25, 3.22, 10.01, and 25.00 cm at 21, 40, and 60°, using the methods already described.<sup>5-9</sup> The  $\epsilon'$  value at 25 cm, or at an even shorter wavelength, depending on the loss, was indistinguishable from the so-called static dielectric constant  $\epsilon_0$  obtained with a heterodyne beat apparatus.<sup>10</sup> For hexamethylcyclotrisiloxane, the loss  $\epsilon''$  was so low that the dielectric constant  $\epsilon'$  at 3.22 cm was used for  $\epsilon_0$ . The values for these quantities given in Table I have been used for Cole-Cole<sup>11</sup> analysis in the IBM 7094 computer. The values of  $\epsilon_\infty$ , the infinite-frequency or optical dielectric constant,  $\tau_0$ , the most probable re-

laxation time,  $\alpha$ , the distribution parameter, and  $C_2$ , the amplitude or relative weight of the contribution of the second relaxation process, if one exists, thus obtained are tabulated in Table II.  $\epsilon_\infty$  is used to calculate the induced polarization  $P_E + P_A = M(\epsilon_\infty - 1)/d(\epsilon_\infty + 2)$  where  $M$  is the molecular weight and  $d$  the density. The total polarization  $P$  is obtained similarly from  $\epsilon_0$ . The electronic polarization  $P_E$  is calculated from  $n_\infty$ , the refractive index at infinite wavelength. The refractive indices  $n$  are measured at at least two wavelengths, the sodium D-line and the  $H_\alpha$  or  $H_\beta$  line, to calculate<sup>12</sup>  $n_\infty$  from

$$n_\infty = \frac{\lambda_1^2 n_1 - \lambda_2^2 n_2}{\lambda_1^2 - \lambda_2^2}$$

The dipole moment  $\mu$  has been calculated by means of the Onsager equation<sup>13</sup> with  $\epsilon_\infty$  used instead of  $n^2$ .

For comparison, values calculated with  $n_\infty^2$  are listed as  $\mu_n$  in Table III. As the measurements were made at three different temperatures, the free energies of activation  $\Delta F^\ddagger$  could be calculated in the usual manner.<sup>14</sup>

## Discussion of Results

**Dipole Moments.** The dipole moments in Table II tend to be much lower than those in the literature, in which the effects of the large atomic polarizations are neglected. When  $n^2$  is used in the moment calculation instead of  $\epsilon_\infty$ , the moment value  $\mu_n$  obtained is almost twice as large and in satisfactory agreement with previous literature values calculated in this way. The values of  $P_E + P_A$  and  $P$  for hexamethylcyclotrisiloxane differ by no more than the total probable error, and

(14) C. P. Smyth, ref 12, p 63.

ry small apparent moment value in Table II is distinguishable from zero. This zero moment is consistent with the planar structure of the molecule deduced by electron diffraction<sup>15</sup> and X-ray analysis<sup>16</sup> and correctly by Kurita and Kondo<sup>3</sup> as indicating a pole moment. With zero dipole moment Kurita and Kondo took the total polarization  $P = P_E + P_A$  and thus obtained a value of 10.9 for  $P_A$ , which is larger than the value 9.7 in Table II because their value of  $P$  was 66.7 as compared to 65.8 in Table II. The estimated atomic polarization for hexamethylcyclotrisiloxane was only 4.9 and that for octamethylcyclotrisiloxane was 14.5, the estimates being made from comparison with hexamethylcyclotrisiloxane. Consequently, their dipole moment values for these two compounds are more than twice as large as those listed for  $\mu$  in Table II. The presumably correct moments  $\mu$  for the four unsymmetrical molecules in Table II are identical.

**Atomic Polarizations.** The atomic polarizations of hexamethyldisiloxane and hexamethyldisilazane are equal, indicating that the Si-N bonds have the same unusual flexibility that the Si-O bonds have. The atomic polarization of hexaethyldisiloxane is 1.5 larger than that of the hexamethyl compound, the small increase coming from the six  $\text{CH}_2$  groups in the former compound. The main distortion in the molecule is evidently associated with the Si-O-Si angle of the molecule. The virtual identity of the atomic polarization of hexamethylcyclotrisiloxane with that of hexamethyldisiloxane and hexamethyldisilazane indicates that the binding of the six Si-O bonds in the planar ring considerably reduces their flexibility. The indication of this reduction of flexibility by comparison is given by the fact that the atomic polarization found in this laboratory<sup>17</sup> for the corresponding chain compound is 19.0, about twice as large. The available instruments did not cover the range required for the extrapolation of the refraction of octamethylcyclotrisiloxane to infinite wavelength. The refraction for the sodium D-line marked with D before, given in Table II, and used to estimate a value of  $P_E$ . A reasonable estimate of the extrapolated  $P_E$  is  $72.5 \pm 0.5$ , which gives the value 22 for  $\mu$  in Table II. This value, which is only a little larger than that found in this laboratory for the corresponding open-chain compound, shows much greater flexibility than that of the symmetrical, planar hexamethylcyclotrisiloxane molecule. Kurita and Kondo<sup>3</sup> set the moment found for this substance as suggesting the existence of its molecules in a mixture of (crown, cradle, and tub) or in a single, slightly more intermediate form between these. There would also be a possibility of shift from one form of the membered ring to another with greater flexibility as found in the present work for the symmetrical, six-membered ring.

**Relaxation Times.** The most probable relaxation time found for hexamethyldisiloxane, 0.7 at  $2^\circ$ , and the 0.14 of the distribution parameter  $\alpha$  agree well with the experimental uncertainty with the values 1.0 and 0.2, respectively, previously obtained<sup>2</sup> with no

measurement below 1.2 cm wavelength. However, the values of  $\tau_0$  at 20 and  $40^\circ$  show an abrupt drop from the  $2^\circ$  value and the distribution apparent at  $2^\circ$  is absent at the higher temperatures. The data at  $2^\circ$  can be well represented in terms of two relaxation times,<sup>18</sup> the longer of which should be associated with a molecular rotational motion and the shorter with an intramolecular motion. The intramolecular process appears to take over almost entirely at 20 and  $40^\circ$ , where the values of  $\tau_0$ , presumably  $\tau_2$ , are consistent with that of  $\tau_2$  at  $2^\circ$  as evidenced by the linearity of the plot of  $\log \tau_2$  against  $1/T$ . The existence of two relaxation processes at lower temperatures is also suggested by the increase of the distribution parameter to 0.4 at  $-60^\circ$  in the earlier measurements.<sup>2</sup> For hexaethyldisiloxane, the large value of the distribution parameter indicates more than one relaxation time, and the data are well represented in terms of two relaxation times. The larger of these is about what might be expected for the rotational relaxation of a molecule of this size. The values of  $\tau_2$  for hexaethyldisiloxane are somewhat larger than those for hexamethyldisiloxane as would be expected from the larger size of the ethyl groups as compared to the methyl. Although the values of  $C_2$  show increase in importance of the shorter relaxation process with rising temperature, the shorter process does not dominate completely in this temperature range as it does in the case of the smaller molecules.

Since the molecular dipole moment of hexamethylcyclotrisiloxane has been concluded to be zero, it is evident that the relaxation time obtained for it in Table III cannot be for molecular dipole rotation. Indeed, the dielectric loss 0.006 at 2.1 mm wavelength and  $70^\circ$  is lower than the value 0.0073 found for nonpolar benzene at  $20^\circ$  at the same wavelength—further evidence of the absence of any permanent moment in the molecule. This relaxation time, although of the same order of magnitude as the others in Table III, is presumably associated with a different mechanism and will be considered with those of other nonpolar liquids to be discussed in another paper.

The molecule of octamethylcyclotrisiloxane is large and its dipole moment is small but real. The single relaxation time found for it (Table III) is too small to correspond to simple rotational orientation of a rigid molecule of this size. In spite of the fact that the molecule is a closed ring, it seems probable that sufficient bending and twisting of the flexible Si-O bonds can occur to produce the equivalent of an orientation of the net molecular dipole moment, somewhat like that proposed<sup>19,20</sup> for diphenyl ether and similar molecules, though different in detail. Hexamethyldisilazane, which has a molecule similar in size to that of hexamethyldisiloxane, shows only a single relaxation time in the temperature range investigated here. It is much larger than the  $\tau_0$  values found for hexamethyldisiloxane, but not far from the value of  $\tau_1$  attributed to the rotational orientation of the molecule of this substance. There is no evidence in these results of the very rapid intramolecular relaxation process indicated for hexamethyl- and hexaethyldisiloxane.

Dasgupta and C. P. Smyth, to be published.

The values of the free energy of activation may be too approximate to have significance. The free energies for the shorter relaxation processes in hexamethyldisiloxane and hexaethyldisiloxane appear unexpectedly to be higher than that for the longer relaxation process in hexaethyldisiloxane and those for the only relaxation process evidenced in octamethylcyclotetrasiloxane and hexamethyldisilazane.

From viscosity measurements on hexamethyldisiloxane and octamethylcyclotetrasiloxane<sup>21,22</sup> values of  $\eta$  have been interpolated by means of the Arrhenius equation to the temperatures corresponding to those of the relaxation times. The ratios  $\tau/\eta$  are shown in Table IV. The ratio of  $\tau_2/\eta$  for hexamethyldisiloxane is much closer to that of  $\tau_0/\eta$  for octamethylcyclotetrasiloxane than is  $\tau_2$  to  $\tau_0$  in Table III. A considerable part of the difference between the two would appear to be due to viscosity. However, the rapid increase of  $\tau/\eta$  with temperature for octamethylcyclotetrasiloxane points also to an intramolecular motion less susceptible to the influence of viscosity than molecular rotation is.

Table IV

Temp, °C	$\tau$ , 10 <sup>-12</sup> sec	$\eta$ , cp	$\tau/\eta$
Hexamethyldisiloxane			
	$\tau_2$		
2	0.45	0.659	0.68
20	0.27	0.512	0.53
40	0.21	0.402	0.52
Octamethylcyclotetrasiloxane			
	$\tau_0$		
23	1.91	2.243	0.85
40	1.72	1.638	1.05
60	1.59	1.180	1.32

The fact that the values of  $\tau/\eta$  in Table IV are smaller by a factor not far from 10 than those found for effectively rigid molecules<sup>23</sup> gives further evidence of relaxation by intramolecular motion. In the reference cited the relaxation times are expressed in 10<sup>-11</sup> sec, instead of 10<sup>-12</sup> sec as in the present paper.

## Conclusions

The low moments of these compounds are due to the reduction of the Si-O and Si-N bond moments by d<sub>r</sub>-p<sub>r</sub> bonding below those to be expected from the considerable difference between the electronegativities of the bonded atoms.<sup>4,24</sup> In the case of hexamethyldisiloxane, the widening of the Si-O-Si angle<sup>24</sup> to about 150° also reduces the resultant moment.

Lazarev and Tenisheva<sup>25</sup> have concluded from an analysis of infrared data that the oxygen in the Si-O-Si

group possesses considerable freedom of displacement in the Si-O-Si plane and perpendicular to it and that the motions involved in such displacements have such low energies as to be substantially excited even at ordinary thermal energies. Analyses of a quasi-linear triatomic molecule<sup>26</sup> and of disiloxane<sup>27</sup> have shown that, if the potential function for siloxane has minima at angles not far from 180° (150° may be near enough), the vibrational spectroscopic properties of the molecule may be indistinguishable from those of a linear molecule (180° angle). The motion may be that of a bent molecule with rotational motion superimposed on the bending vibration about the minimum of potential energy.<sup>24</sup> It would appear that the very short relaxation time  $\tau_2$  for hexamethyl- and hexaethyldisiloxane in Table III may be associated with dipole orientation by bending of the Si-O-Si angle from 150° through a maximum at 180° to another minimum at 150°, while the slower relaxation is molecular rotation, which, in the case of the almost linear, nearly symmetrical hexamethyldisiloxane molecule encounters little hindrance.

In octamethylcyclotetrasiloxane the Si-O-Si angle is found<sup>28</sup> by X-ray analysis to be 142.5°, probably wide enough to permit frequent bending through the potential maximum at 180° to reverse the direction of the dipole and thus give intramolecular relaxation, which may be too close to the frequency for molecular rotational relaxation to permit of analytical separation of the two processes in our data. The Si-N-Si angle is reported<sup>24</sup> to be 120° with the H and the two Si's coplanar with the N in hexamethyldisilazane. This structure does not give two potential minima separated by a maximum which can be crossed easily to give intramolecular dipole orientation or relaxation. The one relaxation time found for the molecule should, therefore, be that for molecular rotational motion. It should be longer than  $\tau_1$  for hexamethyldisiloxane because of the closeness of the latter's shape to that of a cylinder.

The abnormally high atomic polarizations which have received comment evidently arise from infrared absorptions, which have been treated from the spectroscopic point of view in the papers referred to<sup>26-27</sup> and in others. These atomic polarizations are several times larger than the orientation or dipole polarizations which arise from the orientation of the dipoles fixed in the molecules. With these polarizations we are beginning to enter a doubtful territory in which it may be difficult or arbitrary to distinguish between dipole polarization and atomic polarization.

**Acknowledgment.** The writers wish to express their gratitude to Dr. O. K. Johansson of the Dow-Corning Corporation for the hexaethyldisiloxane and to Dr. R. V. Viventi of the General Electric Company for the other four compounds.

# A Study of the Primary Processes in CH<sub>2</sub>O and CD<sub>2</sub>O Photolyses<sup>1</sup>

Benjamin A. DeGraff and Jack G. Calvert

Contribution from the Evans Chemical Laboratory, The Ohio State University, Columbus, Ohio 43210. Received November 25, 1966

**Abstract:** The primary processes occurring on photolysis of CH<sub>2</sub>O and CD<sub>2</sub>O have been delineated at 3340, 3130, 2654, and 2537 Å, through experiments with added olefin, neopentane, and biacetyl. The data provide estimates of primary quantum efficiencies of the processes: CH<sub>2</sub>O +  $h\nu$  → H + HCO (I), and CH<sub>2</sub>O +  $h\nu$  → H<sub>2</sub> + CO (II). Information is also obtained on the nature and the lifetimes of the excited states involved in these processes. The data show process I is favored at the longer wavelengths (3340 Å), while II dominates at the shorter wavelengths (2537 Å). Data from the photolyses of pure formaldehyde and its mixtures with propylene show values of  $\Phi_{CO} - \Phi_H$ , which are significantly greater than zero. The data are most consistent with the occurrence of a newly postulated reaction sequence (H + CH<sub>2</sub>O → CH<sub>3</sub>O; CH<sub>3</sub>O + CH<sub>2</sub>O → CH<sub>3</sub>OH + HCO), which leads to methanol formation and a carbon monoxide excess. The additional possibility exists of a contribution to the carbon monoxide excess from a third primary process, CH<sub>2</sub>O\* + CH<sub>2</sub>O → CH<sub>3</sub>OH + HCO (III), particularly in photolyses at the very long wavelengths (3660 Å).

The structural simplicity of formaldehyde and the extensive knowledge of its spectroscopy give added interest to the study of the primary processes in formaldehyde photolysis. In this case it should be possible to describe the intimate details of the photochemistry which follow light absorption and precede photodecomposition. Considerable information has been reported on both the singlet-singlet (<sup>1</sup>A<sub>2</sub> ← <sup>1</sup>A<sub>1</sub>) and the singlet-triplet (<sup>3</sup>A<sub>2</sub> ← <sup>1</sup>A<sub>1</sub>) transitions.<sup>2</sup>

The photochemistry of formaldehyde has been studied by numerous workers. Particular attention has been given to the secondary or thermal reactions of the hydrogen atom and formyl radical fragments formed in the photolysis.<sup>3</sup> However, there is still no general agreement on the activation energies for the formyl radical decomposition and the hydrogen-atom abstraction reactions.<sup>4</sup> The photolysis of formaldehyde has been interpreted in terms of two distinct primary photodissociative processes<sup>5</sup>

Attempts have been made to determine the relative importance of the two processes using both iodine inhibition<sup>6</sup> and isotope exchange methods.<sup>3d</sup> However, the two studies lead to opposite views as to the relative importance of I and II as a function of photon energy. The results of a more recent study using flash photolysis of CH<sub>2</sub>O-CD<sub>2</sub>O mixtures have been interpreted to show

that process II is dominant at the lower photon energies.<sup>7</sup> This is in contrast with the behavior observed for the C<sub>2</sub>-C<sub>4</sub> aldehydes, RCHO, where the intramolecular formation of RH and CO is favored over the cleavage to form R and HCO at the higher energies of the absorbed quantum.<sup>8</sup> However, the treatment of the H-D scrambling produced in the CH<sub>2</sub>O-CD<sub>2</sub>O mixture flash photolysis experiments, which were used to derive the wavelength dependence of  $\phi_I$  and  $\phi_{II}$ , is very complex and required that certain assumptions of questionable validity be made.

In this work we have studied the primary processes occurring on photolysis of formaldehyde at selected wavelengths within the first absorption band through experiments with added olefin, neopentane, and biacetyl. The data provide direct estimates of  $\phi_{II}$  and also information on the nature and the lifetime of the excited states involved in the formaldehyde photolysis.

## Experimental Section

Formaldehyde was prepared from polyoxymethylene according to the procedure of Spence and Wild.<sup>9</sup> Formaldehyde-*d*<sub>2</sub> was obtained in polymeric form from Merck Sharpe and Dohme, Ltd., with a stated purity of 99% deuterium. All hydrocarbon gases were Phillips research grade and were used without further purification. Biacetyl (Eastman White Label product) was outgassed, dried over calcium sulfate, and bulb-to-bulb distilled at reduced pressure with the middle third retained for use.

The apparatus consisted of a quartz photolysis cell mounted in an air thermostat with the usual associated glass pump, traps, and tubing. These were connected to a conventional high-vacuum system by bakable metal valves. Pressures were read with a triple-spoon gauge-manometer combination. All components which had direct contact with formaldehyde were heated to avoid polymerization. The thermostat was such that the average temperature of the cell remained constant to within ±0.2° of a desired temperature over the 3-5-hr photolysis period.

The light source was a Hanovia S-500 medium pressure arc. The various wavelength regions (3340, 3130, 2654, and 2537 Å) were isolated by chemical filters.<sup>10</sup> The spectral distribution of the lines so isolated was checked using a Hilger medium quartz spectrograph and was in accord with the published information on the filters.<sup>10</sup>

The bulk of the analyses were performed on a modified Aerograph A-90-P2 gas chromatograph. The product gases were

unity for our conditions. At 3340-Å azomethane was used  $\Phi_{N_2}$  assumed equal to unity. Extinction coefficients were measured at each wavelength and temperature using an RCA 935 phototube whose output was displayed on a strip chart recorder. The intensity was also monitored continuously during each run using a photometer.

The experimental conditions and the quantum yields of carbon monoxide and hydrogen products are summarized for pure CD<sub>2</sub>O and CH<sub>2</sub>O-olefin and/or-neopentane mixtures at 3130 Å in Table II. Similar experiments for 3340, 2654, and 2537 Å are listed in Table III. Data for CD<sub>2</sub>O and CD<sub>2</sub>O-olefin mixtures at all four wavelengths are given in Table III.

## Discussion

**The Primary Processes in Formaldehyde Photolysis.** The olefin inhibition studies herein reported allow determination of  $\Phi_{II}$  values and a delineation of wavelength dependence of the two primary photodissociative processes I and II in formaldehyde photolysis. Free-radical production of molecular hydrogen following I was suppressed in this work through the addition of added olefin. The common radical "getter" in thermal and photochemical studies, NO, O<sub>2</sub>, and others are rather unsatisfactory for photochemical applications since their interaction with electronically excited molecules is not well understood. There is evidence that each is capable of strongly perturbing the course of the photolysis.<sup>11</sup> Monoolefins are efficient hydrogen-atom scavengers at high pressures, but the possible perturbing influence of the olefin under these conditions should be examined in light of Cundall's work on the possibility of triplet energy transfer to the olefin must be considered. Our experimental conditions are such that the mean time between collisions of an excited molecule and propylene was of the order of 10<sup>-8</sup> sec. From the experiments with added biacetyl described below, we estimate that the longest lived excited species of formaldehyde formed at 3130 Å, presumed to be

Soc.*, **74**, 455 (1952); (d) McMillan and J. G. Calvert, "Oxidation and Combustion Reviews, Vol. 1, C. F. H. Tipper, Ed., Elsevier Publishing Co., Amsterdam, 1963, p. 83.

(12) (a) R. B. Cundall, F. J. Fletcher, and D. G. Milne, *Trans. Faraday Soc.*, **60**, 1146 (1964); (b) R. B. Cundall and A. S. Davies, *ibid.*, **62**, 2793 (1966); (c) R. B. Cundall and A. S. Davies, *Proc. Roy. Soc. (London)*, **A290**, 563 (1966).

Figure 1. The quantum yield of hydrogen vs. the propylene to formaldehyde ratio for photolyses at 3130 Å and temperatures of 91°, O; and 129°, Δ.

triplet state, has a lifetime of about  $10^{-8}$ – $10^{-9}$  sec. Thus the excited aldehyde will suffer relatively few collisions with propylene before dissociation. The work of Rebbert and Ausloos<sup>13</sup> has suggested that monoolefins are only a factor of about  $10^{-5}$  times as efficient as conjugated olefins in quenching acetone's phosphorescence. Although the work of Cundall's group suggests a much higher efficiency of triplet acetone quenching as measured by isomerization of *cis*-ethylene-*d*<sub>2</sub> and *cis*-2-butene, it is difficult for us to exclude the effects of radical addition to the olefin in their experiments. Direct measurement of acetone phosphorescence as used by Rebbert and Ausloos should be a more reliable measure of acetone triplet. If one accepts the results of Rebbert and Ausloos and arbitrarily assigns unit energy-transfer probability to the conjugated olefins, a molecule such as propylene is expected to be a very poor triplet energy acceptor for formaldehyde and other similar molecules of very short triplet lifetime.

To test the effectiveness of propylene as a radical scavenger in the photolysis of formaldehyde, several series of experiments were performed. Figure 1 shows graphically the results of propylene inhibition on the quantum yield of hydrogen in experiments at 3130 Å and at two temperatures. The limiting quantum yield of hydrogen is the same within the experimental error for experiments at 91 and 129°. The rather small change in temperature is not expected to alter significantly the value of  $\phi_{II}$ , but the result suggests that the efficient scavenging of radicals occurs for the high olefin pressures which give the limiting value of  $\Phi_H$ . The initial pressure of formaldehyde and the incident intensity were both varied by a factor of 2 without changing the limiting value. Mass spectral (isotope ratio) analysis of the product deuterium from the photolysis of  $CD_2O$ – $C_3H_6$  mixtures showed that abstraction from propylene was unimportant under our conditions. Also mixtures of  $CH_2O$ ,  $CD_2O$ , and  $C_3H_6$  at the partial pressures which gave limiting hydrogen quantum yields were photolyzed. On the basis of the very small amounts of HD found for  $CH_2O$  and  $CD_2O$  photolyses,  $\phi_{II}$ , estimated from limiting  $\Phi_H$  data, may be in error due to incomplete scavenging by at most 3–5 and 5–8%, respectively.

(13) R. E. Rebbert and P. Ausloos, *J. Am. Chem. Soc.*, **87**, 5569 (1965).

Figure 2. The quantum yields of primary process II,  $CH_2O$  (or  $CD_2O$ ) +  $h\nu \rightarrow CO + H_2$  (or  $D_2$ ), as a function of wavenumber for photolyses of  $CH_2O$  and  $CD_2O$  in the vapor phase.

The estimates of the primary quantum yields for the molecular process II were obtained from the limiting  $\Phi_H$  or  $\Phi_{D_2}$  values at high olefin concentrations for both  $CH_2O$  and  $CD_2O$  at four wavelength regions, 3340, 3130, 2654, and 2537 Å. Figure 2 shows the resulting quantum yields as a function of wavenumber. Within the scatter of the data, the primary yield is a linear function of photon energy. The observed monotonic increase in the importance of the molecular mode of dissociation with energy is consistent with the trends found for the other simple aldehydes.<sup>14</sup>

McQuigg found that the volume of products from formaldehyde flash photolysis was proportional to the number of quanta absorbed by the formaldehyde, independent of the wavelength of the light absorbed from 2500 to 3300 Å.<sup>7</sup> If  $\phi_I + \phi_{II}$  equal unity at the shorter wavelengths, as seem very likely, then  $\phi_I + \phi_{II}$  is near unity over this whole range of wavelengths. Thus a reasonable estimate of  $\phi_I$  may be derived from the relation  $\phi_I = 1 - \phi_{II}$ . Following this procedure it can be estimated that  $\phi_{II}/\phi_I$  increases from  $\sim 0.7$  at 3340 to 7.3 at 2537 Å for  $CH_2O$ . The question arises as to what factors determine the relative importance of each of these processes. Of course, the two processes may arise simply as competitive reactions which involve the same electronic state or states. Another possible answer to this question is that two different excited states are involved and that the competition between the two decomposition modes is determined by the rates of population of these states and their reactivities. The most obvious choice of states would be the  $^1A_2$  and  $^3A_2$  electronic states. If spin is conserved in processes I and II then triplet decomposition to molecular hydrogen and carbon monoxide is not possible at the photon energies used in this study, and only the free-radical process could originate from the triplet species.

To evaluate the possible role of the triplet formaldehyde in the photolysis of formaldehyde several experiments were performed.

Few aldehydes and ketones show measurable phosphorescence. Formaldehyde phosphorescence has never been reported although it has been searched for in many laboratories. The participation of a triplet state in the photodecomposition of the aldehydes and ketones has been inferred largely from indirect evidence, but this evidence has been rather convincing. Spe-

(14) (a) F. E. Blacet and J. N. Pitts, Jr., *ibid.*, **74**, 3382 (1952); (b) C. S. Parmenter and W. A. Noyes, Jr., *ibid.*, **85**, 416 (1963).

Figure 3. Plot for the biacetyl quenching of the quantum yield of deuterium in the photolysis of  $\text{CD}_2\text{O}$ -biacetyl mixtures at  $109^\circ$  and about 75 mm pressure of  $\text{CD}_2\text{O}$ .

cifically, photosensitized emission from biacetyl and the decomposition of biacetyl have been used as triplet diagnostic tests in the gas phase.<sup>15</sup> The strong emission and low energy (about 2.5 eV) of its first excited triplet state make biacetyl particularly attractive.

In conjunction with a study of the formaldehyde-sensitized emission of biacetyl, to be reported in a subsequent paper, we also studied the effect of biacetyl on the photodecomposition of formaldehyde- $d_2$ . The deuterio isomer was used in this study with a knowledge of the longer excited lifetime for the deuterio compound and with the hope of reducing troublesome abstraction reactions. The data summarized in Figure 3 show that the diketone is effective in deactivating some state of the excited aldehyde formed at 3130 Å;  $\Phi_D$  decreases with increasing biacetyl pressure. At this wavelength biacetyl is almost transparent. However, experiments with biacetyl alone were performed as an added check, and negligible product formation occurred under these conditions. That energy was being transferred from formaldehyde to the biacetyl in the  $\text{CD}_2\text{O}$ - $(\text{CH}_3\text{CO})_2$  mixture photolyses was shown by the presence of  $\text{C}_2\text{H}_6$ ,  $\text{CH}_3\text{D}$ , and excess CO in the products. HD was not found and thus a D-atom sensitized decomposition is unlikely. However the presence of a small quantity of  $\text{CH}_3\text{D}$  indicates that the methyl-sensitized decomposition of formaldehyde may be occurring.

If we write a general mechanism for energy transfer to biacetyl as

one can show that  $1/\Phi_D = k_d[(\text{CH}_3\text{CO})_2]/k_t\phi + \text{constant}$ . Here  $z$  represents the excited state multiplicity. It is assumed that biacetyl does not interfere with the formation of products by the usual paths which are operative in its absence. With this choice of mechanism, coupled with an assumed energy-transfer rate constant of  $10^{14}$  cc/mole sec, and  $\phi = 1$ , the data of Figure 3 lead to an estimate of the lifetime of the excited state of about  $5 \times 10^{-9}$  sec. If one assumes that processes I and II originate exclusively from the triplet and singlet excited states, respectively, and that the biacetyl addition does not alter significantly the mechanism of hydrogen formation from the free-radical

Figure 4. Plots for the quenching of the primary process formaldehyde photolysis at 3130 Å for experiments at  $91^\circ$ ,  $129^\circ$ ;  $\Delta$ ; in each experiment approximately 100 mm of propylene and 80 mm of formaldehyde were present, and varied amounts of neopentane were added to obtain the gas concentration changes.

mechanism, then a plot of the function  $(1 - \phi_{II})/(\phi_I)$  vs.  $[(\text{CH}_3\text{CO})_2]$  yields an estimate of  $k_t/k_d$  from its slope. Assuming  $k_t = 10^{14}$  cc/mole sec,  $k_d(\text{triplet}) \cong 1 \times 10^8$  sec $^{-1}$  and  $\tau(\text{triplet}) \cong 10^{-9}$  sec. Computations based on the sensitized emission yield a similar value.<sup>16</sup> The quenching efficiency greater than can be accounted for through collisional deactivation (see the results of added neopentane described below), and it is most likely a result of electronic energy transfer. Some care must be used in assigning the donor state since both singlet and triplet energy transfer are possible and would lead to a partial decrease in the decomposition quantum yield of the donor. However, the companion study of formaldehyde-sensitized emission of biacetyl conducted under the same experimental conditions as the reported here shows that formaldehyde preferentially excites biacetyl phosphorescence.<sup>16</sup> This is compelling evidence that triplet energy transfer is occurring. Thus it appears probable that triplet formaldehyde is produced and decomposition does originate from this state. As stated previously, spin conservation suggests that this decomposition reaction involves free-radical split (process I); obviously this cannot be tested unambiguously from the data at hand.

Further experiments were designed to elucidate the nature of the state leading to process II, molecular hydrogen formation. The pressure dependence of the quantum yield of hydrogen was studied at 3130 Å, at temperatures of 91 and  $129^\circ$  to evaluate the efficiency of collisional deactivation of this excited state. Hydrogen formation from the free-radical process I was suppressed in all of these runs through the addition of approximately 100 mm of propylene. Neopentane was used as an "inert" gas since it has many degrees of freedom, and under our conditions abstraction reactions involving its primary hydrogens would be unimportant. These results are summarized in Figure 4. It is apparent that some deactivation occurs at  $129^\circ$ , although rather inefficiently. Of course, partial vibrational relaxation of excited formaldehyde would not eliminate process II completely, but lower its efficiency. The  $\phi_{II}$  data for 2537 and 3130 Å suggest that relaxation of vibrational energy of 1 kcal/mole lowers  $\phi_{II}$  by 50%. If one assumes the

(16) From a study which is to be published by A. Zahra of the laboratories.

collision cross section for the deactivation process is  $3.6 \times 10^{-15} \text{ cm}^2$ , and that each collision is effective in deactivating completely the excited molecule, then the data of Figure 4 lead to an excited state lifetime of about  $2 \times 10^{-11} \text{ sec}$ . This must represent a minimum lifetime in view of the nature of the assumptions made. However, it seems clear that the lifetime of the excited state responsible for the concerted process II is very short at 3130 Å, and it is probably near  $10^{-10} \text{ sec}$ .

The present data and the other information on formaldehyde photolysis may be considered in terms of the following general mechanism for the primary processes.

In the mechanism shown, the right-hand superscript denotes the degree of vibrational excitation above the lowest level of that state where  $q > p > \dots n > m > \dots$ . The observed wavelength dependence of  $\phi_{\text{II}}$  (Figure 2) proves that vibrational relaxation of the excited formaldehyde is incomplete before reaction for the conditions employed here. Regardless of the multiplicity of the state or states involved in primary processes I and II, it is evident that the higher the degree of vibrational excitation, the higher is the efficiency of the process II. Of course we expect the rate constant for both processes I and II to be a function of the vibrational level and multiplicity of the particular state involved. Although it is probably an oversimplification, it seems attractive to the authors to suggest that process II originates largely from the excited singlet state, and that I and III are derived largely from the triplet. With this assumption one may rationalize the increase in the extent of II at the shorter wavelengths in terms of the shortened lifetime of the singlet and the increased magnitude of  $k_{\text{II}}$  compared to  $k_1$ . The primary quantum efficiencies of processes I and II are about equal at 3130 Å. If they originate largely from the different states as suggested, then the rate of intersystem crossing must be about the same as the rate of process II; that is,  $k_3 \cong 10^{10} \text{ sec}^{-1}$  a surprisingly high value. In any case the evidence presented here for the short-lived excited states implies that the rate of intersystem crossing of formaldehyde is very fast. For the formaldehyde molecule the similarity in the geometry of the singlet and triplet excited states must favor large Franck-Condon overlap factors.

The molecular orbital picture of the states to which the initially excited  $n, \pi^*$  carbonyl states pass enroute to photodissociation by processes I and II was first put forward by Peters<sup>17</sup> and later expanded by Abrahamson, Littler, and Vo.<sup>18</sup> It depicts the state giving rise to the concerted process as one in which considerable H-H bonding exists, *i.e.*, an  $n, \sigma^*_{\text{CH}_2}$  state.<sup>18</sup> The free-radical process may arise from a state in which H-H

antibonding is dominant such as an  $n, \sigma^*_{\text{CH}_2}$  state. Unfortunately, the relative energies of these states are not known even approximately, and their energies relative to the  $n, \pi^*$  carbonyl states also are a matter of speculation. Abrahamson has pointed out that, due to the nonplanarity of the excited state, some overlap occurs between the  $\sigma^*_{\text{CH}_2}$  orbital and the  $2p_z$  orbital of oxygen. This effect may lower the energy of the  $\sigma^*_{\text{CH}_2}$  state sufficiently so that the energy necessary for the free-radical process is equal to or less than that required for the molecular decomposition. A quantitative interpretation of the primary processes in terms of the transfer of excitation from the excited carbonyl  $^1(n, \pi^*)$  or  $^3(n, \pi^*)$  states to intermediate states will certainly add greatly to our understanding of the internal energy-transfer processes involved in molecular photochemistry. However, the meaningful interpretation of these details must await the more accurate determination of the appropriate molecular orbital energies.

Primary process III is included to account for the apparent presence of H atoms in the photolysis of formaldehyde at the long wavelengths.<sup>3d</sup> At 3600 Å absorption is in the well-known  $\alpha$  band which originates from the ground state with 1 quantum of  $\nu_4$  excitation. Hence a molecule absorbing in this band is about 81.6 kcal/mole above the ground state. It now appears likely that  $87 \pm 1 \text{ kcal/mole}$  is necessary to dissociate formaldehyde,<sup>19</sup> and a process such as III seems necessary to explain the photochemistry of formaldehyde at 3660 Å.<sup>19,20</sup> In view of the low activation energy associated with H-atom abstraction from formaldehyde, it is quite possible that triplet formaldehyde may abstract an H atom from formaldehyde analogous to the triplet state reactions of carbonyl compounds in liquid systems.<sup>21</sup> Primary process III is also in accord with the mechanism proposed by Kistiakowsky and co-workers for the high-temperature pyrolysis of formaldehyde.<sup>22</sup>

**Formaldehyde Photolysis Mechanism and the Excess of Carbon Monoxide over Hydrogen in the Products.** During the course of this study, sufficient data accumulated to allow some interesting and new observations on the mechanism of the secondary reactions in the photolysis of formaldehyde. For the usual conditions employed in this study, notably high formaldehyde pressures and low light intensities, the quantum yield of carbon monoxide exceeded that of hydrogen by an amount far outside the experimental error (see the data of Tables I and II). The product imbalance was much smaller for the  $\text{CD}_2\text{O}$  data (see Table III). Kutschke and Venugopalan also found a carbon monoxide excess at 3130 Å for both  $\text{CH}_2\text{O}$  and  $\text{CD}_2\text{O}$  photolysis at high temperatures which was inversely dependent on the absorbed light intensity.<sup>23</sup> However, McQuigg found the ratio of products  $\text{H}_2/\text{CO} \cong 1.0$  for  $\text{CD}_2\text{O}$  and  $\text{CH}_2\text{O}$  photolyses at the high intensities of flash photolysis.<sup>7</sup> In view of these apparently conflicting results, we

Figure 5. A plot of the carbon monoxide excess function,  $\Phi_{\text{CO}} - \Phi_{\text{H}}$ , vs. the variables of function 13 of the text; data are from 3130-A photolysis of formaldehyde and formaldehyde-neopentane mixtures at 129°.

examined the photolysis of formaldehyde using the full arc in one series of runs. The incident intensity was approximately  $10^4$  times greater than that used for the routine experimental work. Formaldehyde pressures were varied over the range 24–120 mm, with up to 266 mm of added neopentane; the ratio of  $\text{H}_2$  to CO was  $1.03 \pm 0.03$  for all runs, confirming McQuigg's observations from the photolyses at the very high intensities. Thus it appears that the mechanism which leads to carbon monoxide and hydrogen changes as a function of the light intensity.

The carbon monoxide excess is not the result of direct mechanical loss of hydrogen, nor is it formed in these experiments from a dark reaction such as has been observed previously for other conditions.<sup>3d,24</sup> Some process which produces carbon monoxide and not hydrogen or that consumes  $\text{H}_2$  or H atoms must be involved. An H-atom addition to the formaldehyde molecule with the ultimate formation of methanol seems an attractive possibility.<sup>25</sup> Consider the following simplified mechanism to occur following primary process I.<sup>26</sup>

(24) J. E. Longfield and W. D. Walters, *J. Am. Chem. Soc.*, **77**, 6098 (1955).

(25) An extensive effort was made to detect unambiguously the photochemical generation of methanol in the products. Methanol is present after a condensation and work-up of the products for analysis, but it is difficult to evaluate the extent to which it is formed in the photochemical runs. This results from the fact that polymerization of pure formaldehyde induces the thermal formation of small amounts of methanol as identified by infrared and mass spectrometric analyses. Thus the prior removal of formaldehyde to facilitate identification of methanol in the photochemical products is impossible. Furthermore, when small amounts of methanol are added to pure formaldehyde and a polymerization is effected, both formaldehyde and much of the methanol are removed. No quantitative method could be found to determine the methanol unambiguously, but its presence seems highly probable from the qualitative results which were obtained.

(26) At the lowest intensities employed in this work, a first-order chain termination step should be included in the mechanism, since  $\Phi_{\text{H}}$  is nearly independent of  $I_a$  for these conditions. However, the accuracy of the  $\Phi_{\text{CO}} - \Phi_{\text{H}}$  data does not warrant the sophistication and complication of this added reaction.

One can show from the assumption of this mechanism that relation 10 will define the carbon monoxide excess

$$\Phi_{\text{CO}} - \Phi_{\text{H}} = \left[ \frac{[\text{CH}_2\text{O}][\text{M}]\phi_1 k_5}{I_a(k_6 + k_7)k_8} \right]^{1/2} k_8 \quad (10)$$

The data from the 3130-A experiments are in accord with this mechanism and relation 10 as seen in Figure 5. From a thermochemical standpoint, reaction 6 is favored over 7 since the heats of reaction are  $-25$  and  $-16$  kcal/mole, respectively. Radical addition to the carbonyl bond in acetone has not been observed in acetone photolysis, but in this case the addition of the methyl radical would occur with the liberation of only 5 kcal/mole. Radical attack on the carbonyl bond has been observed previously for hexafluoroacetone.<sup>27</sup>

A number of experimental observations are explicable on the basis of the above mechanism. At lower temperatures, reaction 5 will be slow, and chains, if any, will be quite short. Thus  $\Phi_{\text{CO}} - \Phi_{\text{H}}$  will be small. However, at higher temperatures and pressures, the chain sequence 5, 6, 9, 5, ... , may repeat many cycles before chain termination occurs. As the data of Kutschke and Venugopalan show,  $\Phi_{\text{CO}} - \Phi_{\text{H}}$  may become quite large. However, the thermal stability of  $\text{CH}_3\text{O}$  (or  $\text{CH}_2\text{OH}$ ) and the effect of the higher temperatures on the ratio  $k_6/k_7$  may tend to lessen the importance of the aldehyde reduction relative to chain decomposition. At high intensities and lower temperatures, such as used by McQuigg, and in the high-intensity experiments used in the one phase of this work, radical-radical reactions should predominate. Thus reaction 8 is favored as the usual fate of H and HCO radicals, and a hydrogen-carbon monoxide balance is observed at high intensities.

A possible alternative in the mechanism given is the inclusion of the primary process III as a contributor to the carbon monoxide excess observed. Such a primary process alone cannot lead to  $\Phi_{\text{CO}} - \Phi_{\text{H}}$  values greater than unity. Since the data of Kutschke and Venugopalan show that this difference can be greater than unity, this reaction cannot account for all of the effect, but its possible small contribution cannot be excluded from the facts at hand. Indeed, in view of the evidence for energy limitations on process I at 3660 Å, postulation of its occurrence at 3660 Å is attractive.

The quantitative mechanistic treatment of the carbon monoxide over hydrogen excess data for the propylene inhibition studies is impossible with the limited data at hand. However, some interesting observations can be made. In addition to the reaction sequence I, II, 5–9, reactions 11–14 are probably important. The

addition of the propyl radical to propylene, and subsequent addition steps, may also occur, and these would be followed by H-abstraction or chain-termination reactions analogous to eq 12 and 13–14, respectively.

It can be seen from the data of Tables I–III that propylene addition increases the quantum yield of carbon monoxide, although that for hydrogen is

(27) A. S. Gordon, *J. Chem. Phys.*, **36**, 1330 (1962).

suppressed to a limiting value. This probably results in part from the increased rate of reaction 5 with increasing gas concentration, but in addition the rate constant ratio  $k_{12}/(k_{13} + k_{14})$  may be greater than  $(k_6 + k_7)/k_8$ ; that is, the propyl radical may be more effective in propagating the chain decomposition of formaldehyde than is the hydrogen atom.

It is evident from the results described here that the photolysis of formaldehyde is a much more complex system than has been expected previously. Some of the details are clear from this work, but obviously further definitive experiments will be necessary to determine the extent of the process III in the creation of the carbon monoxide excess in the products.

## The $^{13}\text{C}$ -H Satellite Nuclear Magnetic Resonance Spectrum of Nonequivalent Protons in Acetal

Lana S. Rattet, L. Mandell, and J. H. Goldstein

Contribution from the Department of Chemistry, Emory University, Atlanta, Georgia 30322. Received December 22, 1966

**Abstract:** The nuclear magnetic resonance spectrum of the ethoxy protons in acetaldehyde diethyl acetal (acetal) has been investigated. By using, in addition to the normal proton spectrum, the data provided by the  $^{13}\text{C}$ -H satellite spectrum, a unique set of spectral parameters has been obtained, eliminating the previously reported ambiguity in the solution of this problem. The  $^{13}\text{C}$ -H coupling parameters of the two methylene protons are different, providing a new criterion of nonequivalence in structures of low symmetry.

The proton magnetic resonance spectrum of acetaldehyde diethyl acetal, or simply acetal (I), exhibits a much more complex structure in the methylene region

than is to be expected from a simple  $A_2B_2$  spin system. Since there is no evidence of coupling through the oxygen atom, this complexity has been attributed to magnetic nonequivalence of the methylene protons.<sup>1-3</sup> Three analyses of the spectrum of acetal have been described, all of which treat the ethoxy group as an  $ABC_2$  system, but leading to two markedly different sets of values of the proton-proton couplings. In the first approach Shafer, *et al.*,<sup>1</sup> and Waugh and Cotton<sup>2</sup> assumed  $J_{gem}$  to be of the same sign as the vicinal couplings (taken to be positive). Two different values of the vicinal couplings were then required to match the observed spectrum. The coupling values reported in these studies were:  $J_{gem} = 9.4$  cps,  $J_{vic} = 7.35$ , 6.68 cps;<sup>1</sup> and  $J_{gem} = 9.2$  cps,  $J_{vic} = 7.2$ , 6.7 cps.<sup>2</sup> Subsequently, however, Kaplan and Roberts reexamined the problem and reported an acceptable fit using  $J_{gem} = -9.30$  cps, in which case the vicinal couplings are identical,  $J_{ac} = J_{bc} = +7.03$  cps.<sup>3</sup> Since both sets of values led to acceptable agreement with experiment, the outcome was described as indecisive, following the pattern of some other reported nonunique iterative analyses.<sup>4</sup>

In similar situations we have previously demonstrated that the requirement of simultaneously matching  $^{13}\text{C}$ -H satellite patterns and normal proton spectra can yield unique sets of parameters.<sup>5</sup> Several factors suggested the desirability of attempting to resolve the existing ambiguous situation in the case of acetal. Obviously, the occurrence of multiple solutions of the spectroscopic problem is, in general, a deterrent to efforts directed toward the interpretation of nmr parameters. There is, in addition, considerable intrinsic importance and interest in the origin and magnitude of the effects produced by nonequivalent environments such as those existing in acetal. Finally, successful analysis of the satellite patterns would provide still another and different kind of criterion of nonequivalence.

This communication describes the results obtained from such a simultaneous study of the proton and  $^{13}\text{C}$ -H satellite spectra of the ethoxy region of acetal. The proton-proton couplings so obtained are in close agreement with the results of the last analysis cited above ( $J_{gem}$  and  $J_{vic}$  of opposite sign), and the alternative solution was found to be unacceptable. A small ( $\sim 1.4$  cps) but real difference in the  $^{13}\text{C}$ -H couplings was observed for the two geminal protons. These results are discussed in relation to the other relevant nmr data and to the structural situation in acetal.

### Experimental Section

The acetal used was the commercially available material, purified by fractional distillation over a range of  $\sim 0.5^\circ$ . All spectra were observed with a Varian Associates A-60-A spectrometer operating at 60 Mc/sec. Calibrations were performed by the side-band technique using a Hewlett-Packard Model 200J oscillator monitored with a Hewlett-Packard Model 5512A counter. All reported frequencies represent the average of at least four forward and four reverse sweeps. The neat liquid acetal was used throughout with

a small amount of TMS (or benzene in one case) added to serve as the internal reference. Some difficulty was experienced because of the presence of two impurity lines in the satellite region. Since these lines diminished appreciably in relative intensity with purification, they were omitted from further consideration. Only nine lines of the low-field methylene satellite pattern were observable, as the other fifteen were masked by the quartet of the single hydrogen on the central carbon atom.

The average deviations of the measured frequencies (per peak) were: proton patterns, 0.065 cps; satellite patterns, 0.08 cps.

## Results

The proton spectrum of I is essentially similar to that previously reported and will not be described here in detail. The satellite spectrum is given in Table I.

<sup>a</sup> All frequencies are in cps at 60 Mc/sec, relative to TMS.

Each proton gives rise to two patterns displaced by  $\pm 0.5J_{\text{C-H}}$  from its proton resonance position (except for a negligible isotopic effect on the proton shift).

The upper pattern of the methyl group and the lower methylene pattern are well isolated, but the two remaining patterns overlap very badly, as indicated in Table I. This complicated the assignments, and it was necessary in the analysis of the spectrum to proceed on a trial-and-error basis in this region until a consistent set of assignments was obtained for all the spectral lines in Table I.

The final predicted frequencies and intensities are listed in the appropriate columns of Table I. Excluding overlapping lines, the predicted and observed frequencies agree to within  $\sim 0.05$  cps. (The corresponding agreement for the proton pattern is  $\sim 0.02$  cps.)

The above results were obtained using the final values for the nmr parameters shown in Table II. (The uncertainties shown in this table are those derived from the least-squares procedure used.) On the other hand, the couplings first reported by Shafer, *et al.*, clearly failed to reproduce the satellite spectra, and no reasonable variation of these values were found to improve the results. The isotope effect for the methylene proton shifts (not listed) were  $\sim 0.05$  cps and were not considered to be significant; that for the methyl group is also quite small, but probably outside experimental error.

## Discussion

The results described above establish that, to a very high degree of probability, the parameters of Table II constitute a unique set of values for the ethoxy group of acetal. Accordingly, the ambiguity in the solution referred to by Kaplan and Roberts can be considered as essentially resolved. The proton-proton couplings determined here do not vary significantly from those reported by Kaplan and Roberts, the differences being  $\sim 0.13$  and  $\sim 0.01$  cps for  $J_{\text{gem}}$  and  $J_{\text{vic}}$ , respectively. The difference in shifts for the methylene protons also agrees nicely in the two studies, 9.23 cps as against the value of 9.02 cps obtained here.

Waugh and Cotton were the first to correctly identify the origins of the nonequivalence of the methylene protons in structures such as acetal.<sup>2</sup> They pointed out that, although nonequivalence could arise from rotational isomers of different stability, it would still persist in the case of free internal rotation because of the low degree of symmetry of the acetal molecule. These workers also commented that the pmr spectrum of ethylal (II) exhibited an uncomplicated pattern indica-

tive of equivalent methylene protons. We have confirmed this observation by examining the  $^{13}\text{C}$ -H satellite patterns of II, which turns out to correspond qualitatively to an  $\text{A}_2\text{B}_2$  ethoxy system. Frankiss has also reported values of  $140.5 \pm 1.0$  and  $126.0 \pm 0.3$  cps for the two  $^{13}\text{C}$ -H couplings of the ethoxy system in ethylal.<sup>6</sup> These results were quite similar to those obtained here for acetal. More recently, Elvidge and Foster, in their nmr studies of various acetals, have restated the conclusions of Waugh and Cotton regard-

(6) S. G. Frankiss, *J. Phys. Chem.*, **67**, 752 (1963).

\* All values are in cps. The shifts are relative to internal TMS, at 60 Mc/sec.

ing the source of nonequivalence.<sup>7</sup> The present evidence does not permit an assignment of the relative importance of inherent asymmetry and restricted rotation, and it is likely that detailed temperature studies will be required to clarify the problem. (Shafer, *et al.*, reported the proton pattern of acetal is not significantly changed at temperatures as low as  $-80^\circ$ .)

Whatever the origin of the environmental nonequivalence may be, any interpretation of the chemical shift difference,  $\nu_b - \nu_a$ , is complicated by the difficulty of separating magnetic and inductive contributions. Conceivably, a significant fraction of the 9 cps difference could be attributed, for example, to neighboring-group anisotropy effects. Hence, it is problematical whether, on the basis of the shift data, a significant difference in the character of the two methylene C-H bonds can be inferred.

The  $^{13}C-H$  coupling values, again, reflect very decisively the nonequivalence of the two methylene protons. The difference of  $\sim 1.3$  cps, while small, is nevertheless approximately 10% of the total substituent effect produced by an oxygen atom.<sup>8</sup> (It is worthwhile to point out this difference could not possibly be determined by the simple procedure of calibrating the centers of the satellite patterns, if for no other reason, because of the overlapping of the two systems of peaks.) The occurrence of two distinct  $^{13}C-H$  couplings in the methylene group means that the nonequivalence can actually be localized in the two corresponding C-H bonds. By contrast in the case of the shifts, it is possible, as pointed out above, that part or all of the difference resides in the environment and is of largely magnetic origin.

It has been established that  $^{13}C-H$  couplings are, in at least some cases, affected by the medium.<sup>9,10</sup> How-

ever, such affects do not appear to be of magnetic origin, but rather to arise from factors, either specific or general, which influence the charge distribution in the C-H bonds. For chloroform<sup>9</sup> and for several dihaloethylenes and halomethanes<sup>10</sup> it has been found that increasing  $J_{13C-H}$  was associated with the displacement of the shifts to the lower field. In the latter compounds, in fact, a plot of  $J$  vs.  $\nu$  (as concentration is varied) turns out to be quite linear. Any interaction which displaces charge from the proton to its bonded C atom would be expected to produce at least the observed trend, and it can be tentatively assumed that in acetal also the methylene C-H bonds have been polarized in this manner. (It is observed that in acetal the larger  $J_{13C-H}$  is associated with the lower shift value.) However, the factors responsible for this polarization cannot be reliably assigned on the basis of the presently available evidence.

To the extent that these arguments are valid and applicable here, it seems likely that the  $^{13}C-H$  coupling parameter provides a new criterion of nonequivalence, which has the advantage of not being significantly affected by the magnetic contributions which complicate the interpretation of chemical shifts. Further, use of this criterion in similar stereochemical situations appears to be warranted.

# Ligand Effects on the Rate of Metal-Ion-Catalyzed Decarboxylation of Dimethyloxaloacetic Acid

John V. Rund and Kenneth G. Claus

Contribution from the Department of Chemistry, The University of Arizona, Tucson, Arizona. Received August 26, 1966

**Abstract:** The rate of decarboxylation of dimethyloxaloacetic acid catalyzed by metal ions is shown to be sensitive to the ligands attached to the metal. The  $\text{Mn}(\text{phen})^{2+}$  complex (phen = 1,10-phenanthroline) is a more effective catalyst than aqueous manganese, and  $\text{Mn}(\text{phen})_2^{2+}$  is still more active. Catalysis by zinc and magnesium ions is unaffected by coordinated phenanthroline. Substitution of the hydrogens on the phenanthroline with various groups affects the rates of catalysis of both manganese and zinc. Some substituents appear to cause a change in which step of the reaction is rate determining. The authors suggest that conjugation between the phenanthroline and the acid through the metal occurs, and that there is also another influence on the rate.

Many reactions are known during the course of which the reacting molecules are coordinated to metal ions.<sup>1</sup> The effect of the other ligands associated with the metal on the reaction has also been studied.<sup>2,3</sup> This is particularly interesting in the case of metallo enzymes. Enzyme proteins are often said to be activated by metal ions. In some simple cases, at least, the converse seems to be true: metal ions by themselves can carry out a reaction, but the addition of enzyme protein considerably speeds it up. One ligand (the protein) is acting upon the reaction rate of another (the substrate) while both are coordinated to a common metal ion. More elaborate effects, such as substrate discrimination by the enzyme and influence on the steric path of the reaction, are also known, but these will not be considered here. Even for simple protein-induced increases in rate, a number of mechanisms can be envisioned by which the substrate-protein interactions may result. (1) The protein by coordination may change the electron distribution or density of the metal in such a way as to modify the electronic environment of the substrate. (2) The large protein molecule may create a local disruption of the solvent structure and decrease the solvent-rearrangement contribution to the activation energy. (3) The protein may have a functional group which is situated near the site of coordination and assists in the reaction. (4) The metal may change the configuration of the protein in such a way as to unfold an active catalytic site from the interior.

This paper reports an attempt to discover whether electronic influences can be transferred by one ligand to another through a metal ion. The investigation was carried out on an enzyme-like model system. The reaction studied was the decarboxylation of the  $\beta$ -keto acid, dimethyloxaloacetic acid. Oxaloacetic acid is decarboxylated enzymatically in certain biological systems,<sup>4</sup> and the two methyl groups simplify the kinetics by preventing enolization. The metals studied were manganese, zinc, and magnesium. 1,10-Phenanthroline derivatives were used in place of the enzyme protein. It had been shown<sup>5</sup> that when these molecules

were coordinated to a +2 metal ion, they acted in a fashion somewhat similar to real enzymes. The course of the reaction for a hydrated metal ion in aqueous solution is<sup>6</sup>

The metal acts as a positive center which attracts electrons and facilitates the rupture of the bond between the carboxyl group and the rest of the molecule. The same mechanism occurs with the metal-phenanthroline complex. In the enzyme, there is evidence that an amine group is involved at some point in the reaction,<sup>7</sup> but the same sequence of substrate association, decarboxylation, and dissociation undoubtedly occurs.

In order to test the transference of electronic effects from one ligand to another through the metal, a number of derivatives of 1,10-phenanthroline were prepared, most substituted in the 4 and 7 positions. Groups in

1,10-phenanthroline

these positions influence the electron density of the nitrogens *para* to them. Not only are the metal-nitrogen  $\sigma$  bonds affected, but it has been shown by nmr that there is significant mixing between the orbitals of the paramagnetic metal ion and the  $\pi$  system of the phenanthroline.<sup>8</sup> Withdrawal of electron density from

the metal should increase  $k$  and  $K$  (see eq 1), while electron donation should decrease them;  $\pi$  interactions among the ligands must be transferred through the  $d$  orbitals of the metal. In zinc and magnesium these are of too high an energy to play a significant role.  $\sigma$ -Bond effects may occur with any of the metals, possibly through the rehybridization mechanism suggested to explain the *trans* effect in transition metal complexes.<sup>9</sup>

## Experimental Section

**Chemicals.** Metal catalysts were made up from reagent grade salts and their concentrations determined by standard volumetric and gravimetric techniques. Water was distilled before use in kinetic runs. The following phenanthroline compounds were purchased from the G. Frederick Smith Chemical Co. and used without further purification: the 4,7-dimethyl, 2,9-dimethyl, 4,7-diphenyl, and 4,7-diphenyl sodium sulfonate derivatives. Others were prepared by published procedures listed below.

1,10-Phenanthroline<sup>10</sup> had mp 118°, lit. 117°; 5-nitro-1,10-phenanthroline,<sup>11</sup> mp 200°, lit. 199°; 3,8-dicarboxy-4,7-dihydroxy-1,10-phenanthroline, 3,8-dicarboxy-4,7-dihydroxy-1,10-phenanthroline, and 4,7-dihydroxy-1,10-phenanthroline<sup>12</sup> are not readily purified to give analytical samples. 4,7-Dichloro-1,10-phenanthroline<sup>13</sup> had mp 248°, lit. 249–250°; subsequent recrystallizations raised the melting point to 262°. 4,7-Dibromo-1,10-phenanthroline<sup>14</sup> had mp 233°, lit. 236°. A reported method<sup>14</sup> for 4,7-dimethoxy-1,10-phenanthroline involving a sealed tube reaction with a copper catalyst did not give satisfactory results. Instead, 2.0 g of 4,7-dichloro-1,10-phenanthroline and 65 ml of methanol were warmed on a steam bath; 35 ml of 10% sodium methoxide in methanol was added, and the solution refluxed for about 20 hr. The precipitated sodium chloride was filtered off, and the solvent was evaporated. The residue was recrystallized from aqueous ethanol, then benzene, and then 20% aqueous methanol with decolorizing charcoal. The final product is white and melts at 205°. *Anal.* Calcd for  $C_{14}H_{10}N_2O_2$ : C, 70.00; H, 5.00; N, 11.66. Found: C, 70.23; H, 4.99; N, 11.67.

All kinetic measurements were made on reactions in glutarate buffer. Matheson Coleman and Bell glutaric acid was recrystallized from chloroform to give a material melting at 98–99°. A weighed amount of acid was mixed with a measured volume of standardized sodium hydroxide and diluted to an appropriate volume. The measured pH was 5.3.

The preparation of dimethyloxaloacetic acid has already been described.<sup>4</sup>

**Kinetic Runs.** The rate of evolution of carbon dioxide was measured by a simple manometer under conditions of partial vacuum in a vessel resembling a Warburg flask.<sup>8</sup> Five or six runs were made for each set of concentrations, and four to eight different concentrations of catalyst were used for each phenanthroline.

The reactions generally gave good pseudo-first-order plots in  $CO_2$  pressure. Some deviations occurred at the beginning of the reactions, but the pressures began to fall on a straight line within a small fraction of a half-life. First-order kinetics was observed over three or four half-lives in a number of cases, but routine runs were normally carried out for only one or two. A precipitate was observed in some of the reactions, particularly near completion. No change in kinetics seemed to accompany precipitation, and the reactions were not otherwise anomalous.

**Calculations.** The association constant between the catalyst and substrate and the rate constant for decarboxylation of this complex ( $K$  and  $k$  in reaction 1) were calculated using an IBM 7072 computer. A program written by one of the authors calculated the concentrations of all the species present and then corrected the observed rate constant for effects of substrate autodecarboxylation and catalysis due to metal ions not coordinated to phenanthroline. The best straight line fitting the corrected data was determined by a weighted-least-squares method. Weighting factors were calculated from the standard deviation of rates of several identical runs.

The values of  $K$  and  $k$  were calculated from the resulting straight line.

**Treatment of Kinetic Data.** The method of calculating the intrinsic rate constant,  $k$ , and the intrinsic equilibrium constant,  $K$ , may be most easily explained by illustrating the calculation for the hydrated-metal-ion catalyst. The reactions of consequence are

$S$  is the dianion of the substrate dimethyloxaloacetic acid,  $M$  is the metal ion, and  $P$  is the decarboxylated acid. For a rate-determining decarboxylation step, the mechanism requires that

$$\frac{d[CO_2]}{dt} = k[MS] \quad (6)$$

Experimentally, the observed rate constant is defined by

$$\frac{d[CO_2]}{dt} = k_o S_t \quad (7)$$

where  $S_t$  is the total amount of substrate present, and where the rate has been corrected for a small amount of autodecarboxylation of the substrate. Combining these equations, one obtains

$$\frac{1}{k_o} = \frac{S_t}{k[MS]} \quad (8)$$

Expanding  $S_t$  gives

$$\frac{1}{k_o} = \frac{[S] + [HS^+] + [MS]}{k[MS]} = \frac{[S]}{k[MS]} + \frac{[HS^+]}{k[MS]} + \frac{1}{k} \quad (9)$$

Substituting  $[H^+][S]/K_a$  for  $[HS^+]$

$$\frac{1}{k_o} = \frac{[S]}{k[MS]} + \frac{[H^+][S]}{k[MS]K_a} + \frac{1}{k} \quad (10)$$

$1/K[M]$  is substituted for  $[S]/[MS]$  and terms are combined to give

$$\frac{1}{k_o} = \frac{1 + [H^+]/K_a}{kK[M]} + \frac{1}{k} \quad (11)$$

At very high metal-ion concentrations (where all the substrate is in the form of the  $MS$  complex), the observed rate will approach as a limit the rate of the decarboxylation step, and the observed and intrinsic rate constants will become equal. Equation 11 shows that a plot of  $1/k_o$  against  $1/[M]$  will be a straight line. The limit is best found by extrapolating the plot back to  $1/[M] = 0$  to find the intrinsic rate constant,  $k$ . Plots of this kind are shown in Figure 4.

The calculation is more complicated, however, since  $[M]$  may not be found until  $K$  is known. It is possible to change the variable into known total metal concentration. Consider two points,  $(1/[M]_1, 1/k_1)$  and  $(1/[M]_2, 1/k_2)$ , on the straight line which fits the plot of  $1/[M]$  against  $1/k_o$ . Equation 11 indicates that

$$\frac{1}{k} = \frac{1}{k_2} - \frac{1}{[M]_2} \left( \frac{1/k_1 - 1/k_2}{1/[M]_1 - 1/[M]_2} \right) \quad (12)$$

that is, the extrapolation of  $1/k_o$  to  $1/[M] = 0$  gives  $1/k$ . The equilibrium metal concentration may be expressed as

$$[M] = M_t - [MS] \quad (13)$$

where  $M_t$  is the total metal concentration. Using relation 8 for  $[MS]$ , one obtains

$$[M] = M_t - \frac{k_o}{k} S_t \quad (14)$$

Figure 1. Corrected rate constants as a function of catalyst concentration for manganese catalysts. Numbers refer to Table I.

Substitution of (14) into (12) gives

$$\frac{1}{k} = \frac{1}{k_2} - \left( \frac{1}{M_2 - \frac{k_2}{k} S_t} \right) \left( \frac{1/k_1 - 1/k_2}{1/(M_1 - \frac{k_1}{k} S_t) - 1/(M_2 - \frac{k_2}{k} S_t)} \right) \quad (15)$$

where  $M_1$  and  $M_2$  are total metal concentrations corresponding to  $[M]_1$  and  $[M]_2$ . Rearrangement of this equation gives a quadratic in  $k$

$$k^2[(M_1 k_2/k_1) - M_2] + k[k_2(M_2 - M_1)] + [(k_2 k_1 - k_2^2) S_t] = 0 \quad (16)$$

The value of  $k$  which is calculated from this equation is inserted into eq 11 to calculate  $K$ .

When the catalyst is a metal-phenanthroline complex, additional corrections must be made as a result of the incomplete association between the metal and the ligand. Relatively few association constants between metals and substituted phenanthrolines have been measured. The constants which are known are not very different from that of 1,10-phenanthroline itself. Since the corrections involving these constants are minor, the value of the association constant for a metal with 1,10-phenanthroline is used for the value of the association constant for the same metal with substituted phenanthrolines. An exception is made in the case of 2,9-dimethyl-1,10-phenanthroline, where some association data are available. We are led to assume the relatively small value of 300 for its association constant with manganese.

The range in the values for constants  $K$  and  $k$  was estimated by moving the line best fitting  $1/k$ , vs.  $1/[\text{catalyst}]$  within the confines of the standard deviations of  $k$ . It is important to test the results in this way, since the intercepts of the lines are often near zero on the

reciprocal plot, and even small deviations can cause large fluctuations in the values of the constants.

## Results and Discussion

Table I presents the data and calculated results.  $M_t$  in the first column is the total concentration of metal ion in the reaction,  $[\text{cat}]$  is the calculated concentration of metal-phenanthroline catalyst,  $k_o$  is the observed rate constant,  $\sigma$  is its standard deviation,  $k_s$  is the rate constant from which the contributions from other reactions have been subtracted, and  $K$  and  $k$  are the intrinsic reaction constants of eq 1. Figures 1 and 2 show the corrected rate constants,  $k_{\text{corr}}$ , as functions of the catalyst concentrations for manganese and zinc. For clarity the rate constants are plotted without indicating the standard deviations, and the concentrations are placed on a logarithmic scale. Generally speaking, when the data are plotted with their standard deviations on a linear scale, they can be fit by a smooth, monotonic curve. At high concentrations of catalyst, the curve will level off as the corrected rate constant approaches the intrinsic rate constant of decarboxylation,  $k$ . It has been pointed out above that  $k$  can also be determined by extrapolation of the linear plot of  $1/k$ , against  $1/[M]$ , and this method is considerably more accurate.

**Electronic Effects.** The activation of aqueous manganese by one and two coordinated molecules of phenanthroline can be seen in Figure 1 (data numbered 2 and 3, respectively). That there is no activation of zinc

Figure 2. Corrected rate constants as a function of catalyst concentration for zinc catalysts. Numbers refer to Table I.

by phenanthroline is shown in Figure 2, in which the three catalysts,  $\text{Zn(aq)}^{2+}$ ,  $\text{Zn(phen)}^{2+}$ , and  $\text{Zn(phen)}_2^{2+}$  have nearly the same catalytic activity. This result is consistent with the explanation that the function of the metal is to accept electron density from the substrate, and that coordination to a phenanthroline molecule increases the metal's ability to act in this way by an interaction with its d orbitals to delocalize the substrate electron density over a greater volume of space. Manganese(II) interacts readily, but the d orbitals of zinc(II) are of too high an energy to mix extensively with the substrate or phenanthroline  $\pi$  orbitals. To use the terminology developed in physical organic chemistry, the substrate and the phenanthroline are conjugated through the manganese, but not through zinc because of the absence of an appropriate  $\pi$  orbital. If this were the only influence operating on the decarboxylation rate, one would expect that upon substitution of the phenanthrolines at the 4 and 7 positions additional changes in rate would occur for the manganese catalyst but not for the zinc, as a result of the resonance effect. Many of the zinc catalysts in fact have quite similar rates, but at least the dichloro and dimethoxy derivatives show marked differences. Some other influence must also be operating on the substrate as a result of the substitution of remote positions on the phenanthroline. It should be noted that the resonance effect can be made to correlate a considerable amount of the data. Ligands may be picked out which seem to be affected to the same extent by whatever influence is operative beyond the resonance effect. These are the aqueous catalyst, the phenanthroline complex, the bis(phenanthroline) complex, and the complexes of

4,7-dihydroxy and 4,7-dibromo derivatives, which all have the same rates for zinc, where resonance does not operate. Examining the rates of the corresponding manganese complexes, one finds them in an order consistent with resonance activation. The aqueous catalyst is slow,  $\text{Mn(phen)}^{2+}$  is faster, and  $\text{Mn(phen)}_2^{2+}$  is still faster. The bromo derivative seems a little slower and the dihydroxy derivative much slower than the unsubstituted phenanthroline.

Some other cause must be invoked to help account for the results. The inductive effect, which could operate in both the zinc and manganese catalysts, seems to be a logical complement to the resonance effect. The methoxy group attracts electrons inductively, and this might be responsible for its activation of the catalyst. The apparently contradictory inhibiting effect of hydroxide substitution may be due to partial ionization of the protons on the hydroxide, which would lower the positive charge on the catalyst.

Another possible cause of activation is the disruption of the solvent structure in the region of the metal ion. Reorientation of the water molecules during decarboxylation may contribute to the activation energy of the reaction, and the exclusion of water by phenanthrolines may lower the activation energy. Large substituents on the phenanthrolines should increase water exclusion. The two most effective zinc catalysts do in fact contain the largest substituents, methoxy and phenyl groups. Neither of these arguments, however, will explain the results of methyl substitution at the 4 and 7 positions, which increases the catalytic activity of the manganese complex and decreases that of the zinc complex. It may be that the 4,7-dimethyl-

<sup>a</sup> Initial concentration of dimethyloxaloacetic acid was  $7.81 \times 10^{-3} M$  in every case. Metals were introduced as solutions of the salts. <sup>b</sup> Calculated on the assumption of an association-limited mechanism. <sup>c</sup> Mechanism is dissociation limited. <sup>d</sup> Results erratic for a meaningful calculation. <sup>e</sup> Compare with aqueous magnesium rates at the same catalyst concentrations.

phenanthroline-zinc catalyst is a very effective boxylating agent, but that its affinity for the boxylated product is large enough to prevent a or extensive regeneration of the catalyst. The sponding manganese catalyst would be more easily erated because of the larger size of the metal ion. ore compelling conclusion will have to await denation of the rate-determining step by the mass-ometric method.

**Rate-Determining Step.** In the cycle of decaration catalysis, any of three steps may limit the the association of the substrate and the catalyst, ecarboxylation of the complex, or the dissociation e catalyst and the decarboxylated substrate. In ystem under study, the rate-determining reaction usually be distinguished. A rate-limiting associa- will be first order in catalyst concentration and a of  $k_e$  vs. [catalyst] (or of  $1/k_e$  vs.  $1/[\text{catalyst}]$ ) will

$$\text{rate} = k[\text{LM}][\text{S}] = k_{\text{obsd}}[\text{S}] \quad (18)$$

$$k_{\text{obsd}} = k[\text{LM}] \quad (19)$$

straight line going through the origin. This would when association was for some reason very un- able, for example, due to steric effects.

When decarboxylation is rate-determining, the graph vs. [catalyst] will be curved. This is indicated by which results from [LM] being a function of [S],

$$\text{rate} = k[\text{LMS}] = kK[\text{LM}][\text{S}] \quad (21)$$

$$k_{\text{obsd}} \neq kK[\text{LM}] \quad (22)$$

prevents eq 21 from being integrated as a first- equation in [S]. The graph of  $1/k_e$  vs.  $1/[\text{catalyst}]$  e a straight line with a nonzero intercept. Deriv- of the proper equation has already been dealt with. the dissociation step, which regenerates the st, should become rate determining, a rapid l decarboxylation will occur until the catalyst is ated with decarboxylated substrate. The rate will decrease as it becomes limited by catalyst regenera-

tion. This initial fast rate would be expected to be visible when the catalyst is at a concentration which is smaller, but not a great deal smaller, than the substrate.

Caution must be exercised in the interpretation of the rate-determining step. In particular, a fast rate-determining decarboxylation will have a very small intercept on the plot of  $1/k_e$  vs.  $1/[\text{catalyst}]$ , and may thus be confused with a rate-determining association. Generally speaking, the latter should be slow and the former fast, if an appropriate standard of "normal" speed can be found.

**Rate-Determining Association.** One catalyst seems to have its activity limited by the rate at which the substrate can coordinate to the metal ion: the 2,9-dimethyl-1,10-phenanthroline-manganese complex. Its rate is plotted in Figure 3 and may be seen to fit the expected pattern fairly well. The rate is slowed by steric hindrance. The methyl groups project out beyond the metal and must considerably impede the approach of the substrate to the metal. The reaction is kinetically well behaved. Steric and neighboring-group effects will be treated in a later paper. The intrinsic constant for this catalyst is  $0.00280 \text{ sec}^{-1}$ . This number refers to  $k$  in eq 15. It can be compared to the product  $kK$  for a reaction with a rate-determining decarboxylation step and is seen to be much smaller than the rates of other mono(phen) derivatives. Another catalyst which may be in this category is the  $\text{Mn}(\text{phen})_2^{2+}$  complex (see Figure 3). Its reaction rate is also first order in catalyst. Its reactions are fast, however, and its intrinsic rate constant, assuming this mechanism, is  $0.0165 \text{ sec}^{-1}$ . It is possible that this is a case of rate-determining decarboxylation which is fast enough that the intercept of the reciprocal plot is not distinguishable from zero. These two alternatives can be decided between using the kinetic isotope approach employed by Westheimer.<sup>15</sup>

**Rate-Determining Decarboxylation.** The aqueous metal ions and catalysts 2, 4-6, 7, 11, 12, 14-16, 18, 21, and 22 have rate-determining decarboxylation steps. Some reciprocal plots are illustrated in Figure 4. Coordination of the enzyme protein to a metal ion causes this step to become so much faster that it is no longer rate determining.<sup>15</sup> Thus the factors which influence the rate of this step are of particular interest in under-

(15) S. Seltzer, G. A. Hamilton, and F. H. Westheimer, *J. Am. Chem. Soc.*, **81**, 4018 (1959).

Figure 3. Catalysts conforming to the expected pattern for rate-determining association. Numbers refer to Table I. Units on the left ordinate refer to catalyst 9, and those on the right to 3.

standing the function of the protein. The intrinsic reaction constants are a disappointment in this regard because of their great sensitivity both to the exact fit of the line to the reciprocal plot and to the value chosen for the rate of the autodecarboxylation. The rate of autodecarboxylation was influenced by the addition of ligand, even when no metal ion was present. The error in this correction cannot have been large, but, in an unfavorable case, it might have made a considerable error in the intrinsic rate constants, larger than that indicated in Table I.

In examining the intrinsic rate constants for manganese, it may be seen that the  $\text{Mn}(\text{phen})^{2+}$  catalyst has the largest  $k$ . Even the groups on the phenanthroline which are expected to be electron withdrawing, Br and Cl, seem to be slower than H. This may perhaps be explained on the basis of the high charge on the metal ion, which might polarize these groups more than it can the hydrogen and cause them to be relatively electron donating. The range for most of the constants is so great for zinc that no general statement about those catalysts is possible. The results are not readily explained.

The intrinsic equilibrium constants are smaller than the ones reported between these metals and similar  $\beta$ -keto acids.<sup>16</sup> It has already been pointed out<sup>5</sup> that this is a result of the difference in what is being measured. The kinetic method used here measured only coordination of the acid in the manner favorable for decarboxylation (see reaction 1), while the potentiometric method measured coordination through any atoms. The difference in the two equilibrium constants, which is about an order of magnitude, suggests that the substrate spends most of its time on the metal

(16) E. Gelles and R. W. Hay, *J. Chem. Soc.*, 3673 (1958).

Figure 4. Some representative plots for catalysts with rate-determining decarboxylation steps. Numbers refer to Table I.

Figure 5. A kinetic run for manganese-4,7-dimethoxy-1,10-phenanthroline catalyst at a concentration of 0.00657  $M$ . This illustrates the predicted pattern for a rate-determining dissociation step.

in a position in which it cannot be decarboxylated. If an enzyme protein were capable of causing the substrate to approach the metal only in a disposition favorable to reaction, the rate would be greatly enhanced.

**Rate-Determining Dissociation.** There are three mono(phen) catalysts which are much more active than any of the others. These are the 4,7-dimethoxyphenanthroline complexes of manganese and zinc and the 4,7-dimethyl complex of manganese. None of these fits either of the previous patterns of variation in rate as a function of catalyst concentration. An initial large rate, slowing as the catalyst becomes saturated

decarboxylated substrate, was observed for a part of the reactions. The effect was most pronounced where the catalyst was present to the extent of 60–80% of the substrate. Figure 5 illustrates a reaction where this is occurring. Both manganese salts exhibited this behavior, but it was not observed for zinc, where the highest concentration of catalyst was only 20% of the substrate. It may be that the initial fast reaction was over before any measurements were made. Certainly when the manganese salts were at this concentration, the fast initial reaction was difficult to see. The values given in Table I for the slower part of the reaction. Initial rates as much as five times this fast.

These complexes are the most like the enzyme, inasmuch as they are the most efficient catalysts and appear to have the same rate-determining step. The other complexes at least do not derive their activation from the resonance effect, which does not occur for them and would be expected to deactivate the complex manganese.

**Other Catalysts.** At low concentrations, some of the complexes showed deviations from the expected patterns of behavior. The corrections for these were large relative to the rate constant itself. Their observed rates are reported in Table I, but the corrected constants are omitted. These data were not used to compute the rate constants. The sodium salt of the sulfonated phenyl-1,10-phenanthroline complexes gave such results that computations based on them are meaningless.

## Conclusions

It has been shown that when two ligands are coordinated to a single metal ion, changes in one can affect the reaction rate of the other, even when the changes in the first are remote from the second. Coordination of a manganese ion with a phenanthroline molecule greatly increases its ability to catalyze the decarboxylation of a  $\beta$ -keto acid. Catalysis by zinc, however, is unaffected by coordination with phenanthroline. Substitution of the phenanthroline at the 4 and 7 positions is also shown to change the rate. The resonance effect, which allows electron density from the acid to be delocalized into the system of the metal-phenanthroline complex, is suggested as a contributing influence. A second influence, the nature of which has not yet been determined, also affects the catalytic behavior of these compounds. The inductive effect is not usefully invoked to do this. Some very effective catalysts for decarboxylation have been found, and these are activated by the second influence. The data strongly suggest that they have the same rate-determining step as the decarboxylase enzyme. The enzyme protein does not activate the metal ion in the same way as phenanthroline itself does, but the second and unidentified influence, exerted for example by the methoxy phenanthrolines, may be a contributor to the activation by the enzyme.

## Preparation and Characterization of New Fluoroxy Compounds. Bis(fluoroxy)perfluoroalkanes<sup>1,2</sup>

Phillip G. Thompson and Julianne H. Prager

*Contribution No. 394 from the Central Research Laboratories, Minnesota Mining and Manufacturing Company, Saint Paul, Minnesota 55119. Received August 1, 1966*

**Abstract:** The synthesis and characterization of  $\text{CF}_2\text{CF}(\text{OF})_2$  and  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ , representing the new class of geminal bisfluoroxy compounds, are reported. Their formation from  $(\text{CF}_3)_2\text{C}(\text{OH})\text{ONa}$  illustrates the unique behavior of salts in direct fluorination.

We have reported<sup>3</sup> the preparation and reactions of the monofluoroxy compounds:  $\text{CF}_2\text{CF}_2\text{OF}$ ,  $\text{CF}_2\text{CF}_2\text{OF}$ ,  $(\text{CF}_3)_2\text{CFOF}$ ,  $(\text{CF}_3)_2\text{COF}$ ,  $\text{NO}_2\text{CF}_2\text{OF}$ ,  $\text{ClCF}_2\text{CF}_2\text{OF}$ ,  $\text{Cl}_2\text{CFCF}_2\text{OF}$ , and  $\text{Cl}_2\text{CF}_2\text{OF}$ , as well as<sup>4</sup>  $\text{FC}(\text{O})\text{CF}_2\text{CF}_2\text{OF}$  and  $\text{FOCF}_2\text{CF}_2\text{OF}$ .

Some of the material in this paper was included in the review "Oxygen Fluorides and Hypofluorites" by P. G. Thompson at the Symposium of the Inorganic Division of the American Chemical Society, Ann Arbor, Mich., June 27, 1966. (b) In accordance with the recommendations of the American Chemical Society Committee on Nomenclature of Highly Fluorinated Molecules, the term fluoroxy is used for the OF group.

This research was supported by the Advanced Research Projects Agency under Contract NOrd 18688 and was monitored by the Bureau of Chemical Warfare.

J. H. Prager and P. G. Thompson, *J. Am. Chem. Soc.*, **87**, 230 (1965).

J. H. Prager, *J. Org. Chem.*, **31**, 392 (1966).

$\text{CF}_2\text{CF}_2\text{OF}$ . Cady and co-workers previously described the synthesis of  $\text{CF}_2\text{OF}$ <sup>5</sup> and several unstable acyl OF compounds.<sup>6</sup> In this paper the preparation of two members of a new class of compounds, the bis(fluoroxy)perfluoroalkanes, is reported. The characterization and certain reactions of these compounds,  $\text{CF}_2\text{CF}(\text{OF})_2$  and  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ , are also presented. In addition, an improved synthesis of  $\text{C}_2\text{F}_5\text{OF}$ <sup>7</sup> is reported.

## Discussion

The direct fluorination of perfluoroacetone hydrate,  $(\text{CF}_3)_2\text{C}(\text{OH})_2$ , yields  $(\text{CF}_3)_2\text{CFOF}$ .<sup>8</sup> We now report

(5) K. B. Kellogg and G. H. Cady, *J. Am. Chem. Soc.*, **70**, 3986 (1948).

(6) (a) G. H. Cady and K. B. Kellogg, *ibid.*, **75**, 2501 (1953); (b) A. Menefee and G. H. Cady, *ibid.*, **76**, 2020 (1954).

the direct fluorination of the monosodium salt of perfluoroacetone hydrate,  $(\text{CF}_3)_2\text{C}(\text{OH})\text{ONa}$ ,<sup>7</sup> to give  $(\text{CF}_3)_2\text{C}(\text{OF})_2$  and  $\text{CF}_3\text{CF}(\text{OF})_2$  in addition to the previously reported<sup>1</sup>  $(\text{CF}_3)_2\text{CFOF}$  and  $\text{C}_2\text{F}_5\text{OF}$ . The two compounds, 2,2-bis(fluoroxy)perfluoropropane and 1,1-bis(fluoroxy)perfluoroethane, represent the first examples of compounds containing two fluoroxy groups bonded to the same atom.<sup>8</sup>

The surprising difference in the products obtained from the direct fluorination of these two structurally similar materials illustrates the advantage of using salts to prepare fluoroxy compounds, particularly when bis-fluoroxy structures are desired.

A further demonstration of this point is found in a comparison of the fluorination products of trifluoroacetic acid and its salts.<sup>1,9</sup> The acid affords rather low yields of the unstable hypofluorite,  $\text{CF}_3\text{C}(\text{O})\text{OF}$ ,<sup>6a,10</sup> whereas the salts give yields of up to 60%  $\text{CF}_3\text{CF}(\text{OF})_2$ . The combined yield of OF compounds obtained from the perfluoroacetate salts can approach 95% of theory.<sup>1,9</sup>

It was earlier pointed out that OF-containing compounds are formed in best yield when starting materials low in C-H content are used.<sup>3</sup> The compound  $(\text{CF}_3)_2\text{COF}$ , for example, is obtained in excellent yield from  $(\text{CF}_3)_2\text{COH}$ . The fluorination of nitrosyl perfluoroacetate,  $\text{CF}_3\text{C}(\text{O})\text{ONO}$ , described in this paper, gives  $\text{CF}_3\text{CF}_2\text{OF}$  in approximately 20% yield, while  $\text{CF}_3\text{CH}_2\text{OH}$  gives only about 10% of this product. The fluorination of a material high in C-H content, *i.e.*,  $\text{HOCH}_2\text{CH}_2\text{CH}_2\text{OC}(\text{O})\text{CCl}_3$ , was shown to produce  $\text{FOCF}_2\text{CF}_2\text{CF}_2\text{OF}$  only in very small amount.<sup>4</sup>

The direct fluorination of the monosodium salt of perfluoroacetone hydrate proceeds rapidly at room temperature. The products include  $\text{CO}_2$ ,  $\text{COF}_2$ , and, in order of decreasing yield, the following OF-containing compounds:  $(\text{CF}_3)_2\text{CFOF}$ ,  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ ,  $\text{CF}_3\text{CF}_2\text{OF}$ , and  $\text{CF}_3\text{CF}(\text{OF})_2$ . The combined yield of fluoroxy compounds obtained in this reaction is substantial, amounting to about 35% of the isolated product. It is interesting to note that under the conditions used in this fluorination reaction more of the three-carbon fluoroxy compounds were formed than of the two-carbon species. Although  $\text{CO}_2$  and  $\text{COF}_2$  were formed in rather large amounts, fluorination to  $\text{CF}_3\text{OF}$  apparently did not take place.

(7) The preparation of this compound is described for the first time in this paper. Additional reactions will be published later by J. H. Prager and P. H. Ogden.

(8) There is a marked contrast between hypofluorites containing normal fluoroxy groups and the extremely unstable, low-temperature oxygen fluoride,  $\text{O}_2\text{F}_2$ , as discussed in ref 1.

(9) P. G. Thompson, to be published.

(10) G. L. Gard and G. H. Cady, *Inorg. Chem.*, **4**, 594 (1965).

These various fluoroxy compounds present an interesting contrast in properties. The perfluoroethylidene compound,  $\text{CF}_3\text{CF}(\text{OF})_2$ , is not especially susceptible to explosive decomposition, and it is considerably more stable thermally than  $\text{CF}_3\text{CF}_2\text{OF}$ . On the other hand, the perfluoropropylidene compound,  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ , is very prone to explode and, in fact, is more difficult to handle than any of the other fluoroxyperfluoroalkyl compounds investigated in our laboratory. The reason for this sensitivity is not understood. It does not appear to be due to steric crowding since no such difficulties were observed with  $(\text{CF}_3)_2\text{COF}$ .<sup>3</sup>

The tendency of  $(\text{CF}_3)_2\text{C}(\text{OF})_2$  to explode is so pronounced that a dilution technique was used in the work-up of these fluorination runs. The inert solvent,  $\text{CFCl}_3$ , was condensed into the trap containing the mixture of volatile fluorination products, and only then was the separation of the products attempted. In general, no difficulty was experienced in isolating and purifying  $\text{CF}_3\text{CF}_2\text{OF}$ ,  $(\text{CF}_3)_2\text{CFOF}$ , and  $\text{CF}_3\text{CF}(\text{OF})_2$  by fractional distillation-condensation using vacuum-line techniques followed by gas chromatography. However, any operation which tended to concentrate  $(\text{CF}_3)_2\text{C}(\text{OF})_2$  was found to be difficult and, in fact, many attempts were necessary before the infrared and nmr spectra of this compound were successfully obtained on the same sample. Because of this great sensitivity little information was obtained on the reactions of this material.

## Results

**1,1-Bis(fluoroxy)perfluoroethane,  $\text{CF}_3\text{CF}(\text{OF})_2$ .** Isolation of pure  $\text{CF}_3\text{CF}(\text{OF})_2$  was accomplished by gas chromatography. 1,1-Bis(fluoroxy)perfluoroethane is a colorless gas boiling at approximately  $-35^\circ$ . The melting point of a sample of  $\text{CF}_3\text{CF}(\text{OF})_2$  containing small amounts of  $\text{SiF}_4$  and  $\text{COF}_2$  was between  $-83$  and  $-77^\circ$ . The infrared spectrum of  $\text{CF}_3\text{CF}(\text{OF})_2$  contains absorptions at 7.44 (m), 7.79 (w), 8.06 (vs), 8.30 (s), 8.73 (s), 9.24 (s), 10.83 (w), 11.17 (m), and 13.58  $\mu$  (m).<sup>11</sup> The peak at 11.17  $\mu$  is attributed to the OF group.

The diagram in Figure 1 shows the analysis of the splittings observed in the  $\text{F}^{19}$  nmr spectrum of  $\text{CF}_3\text{CF}(\text{OF})_2$ . The spectrum contains an absorption at  $\phi^* -150.4$  which is assigned to the OF group. The  $\text{CF}_3$  group signal is at  $\phi^* 77.4$  and the CF at  $\phi^* 111.9$ . The coupling constant between  $\text{CF}_3$  and CF is less than 1 cps; that between OF and  $\text{CF}_3$  is 10.3 cps and that between OF and CF is 26.2 cps. The absorption of the  $\text{CF}_3$  group is split into a triplet by the two equivalent OF groups; additional splitting from the CF was not resolved with our instrument (40.0 Mc). The CF signal is likewise split into a triplet by the two OF groups. The absorption of the OF groups is split into a doublet by the CF and each mode further split into a quadruplet by the three equivalent fluorine nuclei of the  $\text{CF}_3$  group. The peak areas were found to be in the ratio of 2.0:1.0:3.0.

1,1-Bis(fluoroxy)perfluoroethane shows much greater thermal stability than fluoroxyperfluoroethane.<sup>3</sup> Several samples, stored in sealed glass nmr tubes with

(11) The relative intensities of the absorptions are indicated by the symbols, vs, s, m, and w, standing for very strong, strong, medium, and weak, respectively.

CFCl<sub>3</sub>, showed only minor decomposition after approximately 5 years at ambient temperatures. Differential thermal analysis indicated no decomposition up to 200°, at which temperature the sample underwent a very rapid exothermic reaction, probably exploding. In this case the CF<sub>3</sub>CF(OF)<sub>2</sub> may have reacted with the metal cup in the dta apparatus; the products formed (as shown by infrared) were CF<sub>4</sub>, COF<sub>2</sub>, CO<sub>2</sub>, and a trace of SiF<sub>4</sub>. When CF<sub>3</sub>CF(OF)<sub>2</sub> is flashed or ignited, quantitative analysis of the products formed indicates that thermal decomposition proceeds predominantly by

The results of additional stability tests (on rate of decomposition in glass) at elevated temperatures are given in Table I. An analysis of the products formed (SiF<sub>4</sub>,

Table I. Thermal Stability Tests of CF<sub>3</sub>CF(OF)<sub>2</sub><sup>a</sup>

Temp, °C	Time, hr	% of CF <sub>3</sub> CF(OF) <sub>2</sub> recovered
150	6.5	95
175	15	70
190	12	32

<sup>a</sup> Sealed in glass nmr tubes; 10–15 mole % solution in CFCl<sub>3</sub> as internal reference.

CO<sub>2</sub>, O<sub>2</sub>, trace of BF<sub>3</sub>, no CF<sub>4</sub>) indicated that the OF compound was reacting with the Pyrex glass tube

rather than undergoing thermal decomposition (expected products: CF<sub>4</sub>, COF<sub>2</sub>, and O<sub>2</sub>). The activation energy for the observed reaction with glass was calculated to be 38 kcal/mole.

The polarographic half-wave potential of CF<sub>3</sub>CF(OF)<sub>2</sub>, measured by means of an indicating electrode vs. a saturated calomel electrode as reference, was found to be approximately 0.5 v, which is consistent with our earlier reported values<sup>1</sup> for CF<sub>3</sub>OF and C<sub>2</sub>F<sub>5</sub>OF. Since the electrochemical reduction of these OF compounds is not reversible, oxidation potentials are not readily obtainable from the polarographic half-wave potential. However, as with other OF-containing compounds, 1,1-bis(fluoroxy)perfluoroethane is strongly oxidizing toward substances such as mercury, ferrocene, potassium iodide, and sodium hydroxide.

Reduction of CF<sub>3</sub>CF(OF)<sub>2</sub> has been found to occur both by (1) normal reductive defluorination with a two-electron change per OF group, and by (2) reductive decomposition wherein oxidation–reduction occurs within the molecule *via* the fragmentation of CF<sub>3</sub>CF(OF)<sub>2</sub>, resulting in cleavage of the carbon–carbon bond. The mechanism for reductive decomposition is apparently not so straightforward as in the case of the monofluoroxy compounds discussed previously,<sup>1</sup> and it has not been determined whether a chain mechanism is involved.

The predominant mode of reduction appears to depend upon the effective contact of the OF compound with the reducing agent. With mercury, unless the reaction vessel is agitated, the film of mercurous fluoride hinders the reductive defluorination mode, and con-

Figure 1. Nmr spectrum of CF<sub>3</sub>CF(OF)<sub>2</sub>.

siderable CF<sub>4</sub> and CO<sub>2</sub> are formed, together with smaller amounts of CF<sub>3</sub>CFO, (CF<sub>3</sub>CO<sub>2</sub>)<sub>2</sub>Hg, and C<sub>2</sub>F<sub>6</sub>. The reaction with ferrocene also proceeds predominantly by the reductive decomposition path, CF<sub>4</sub> and CO<sub>2</sub> being the principal products in addition to ferrocenium fluoride. With excess potassium iodide (in water or in acetonitrile–water media) the two-electron (per OF group) reductive defluorination mode takes place almost exclusively. The over-all reaction can be expressed by

Since this oxidation of iodide to iodine occurs rapidly and without appreciable side reactions, the process can be used for a quantitative measure of the oxidizing power of the fluoroxy compound. Determination of the oxidizing power of a sample of chromatographed CF<sub>3</sub>CF(OF)<sub>2</sub><sup>12</sup> by this reaction gave a value of 22.0 mequiv of iodine per gram of sample (calculated for two-electron change per OF group, 23.0).

An attempt to follow the mode of decomposition in an infrared gas cell equipped with NaCl windows led to the formation of considerable CF<sub>3</sub>CO<sub>2</sub>Na on the windows after several days. The products detected indicate that the following reaction, analogous to that above with KI, occurred.

1,1-Bis(fluoroxy)perfluoroethane reacts only very slowly with water or acidic media, but rapidly oxidizes aqueous base, liberating oxygen<sup>3</sup> according to the following equation.

The reaction is essentially stoichiometric. Oxygen was determined by gas chromatographic analysis, fluoride by conventional thorium nitrate titration, and sodium trifluoroacetate by infrared analysis of the solids. It should be noted that the reaction between the fluoroxy compound and aqueous base is a redox reaction, also analogous to the reaction of CF<sub>3</sub>CF(OF)<sub>2</sub> with aqueous potassium iodide, and does not involve

(12) A value of 21.1 mequiv of I<sub>2</sub>/g was initially obtained; upon standing overnight a value of 22.0 mequiv of I<sub>2</sub>/g (after possible air oxidation was corrected by a blank) was obtained. Apparently approximately 4% of the CF<sub>3</sub>CF(OF)<sub>2</sub> undergoes side reactions under the conditions employed.

Figure 2. Nmr spectrum of  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ .

hydrolysis. Thus, the oxygen formed in this reaction would be expected to come from the NaOH and not from the OF compound.

**2,2-Bis(fluoroxy)perfluoropropane,  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ .** 2,2-Bis(fluoroxy)perfluoropropane is a colorless gas which is strongly oxidizing and shows a pronounced tendency to explode. After considerable difficulty, infrared and nmr spectra were successfully obtained on the same sample of this material. The infrared spectrum shows peaks at 7.77 (vs), 7.92 (vs), 8.14 (sh), 8.89 (s), 9.28 (s), 9.79 (s), 11.26 (m), and 13.50  $\mu$  (m).<sup>11</sup> It is interesting to observe how closely the spectrum of  $(\text{CF}_3)_2\text{C}(\text{OF})_2$  resembles the spectra of  $(\text{CF}_3)_2\text{CFOF}^8$  and  $(\text{CF}_3)_2\text{CF}_2$ .<sup>18</sup> However,  $\text{C}_2\text{F}_8$  shows no absorption in the 11- $\mu$  region, whereas the spectrum of  $(\text{CF}_3)_2\text{CFOF}$  shows medium intensity absorption at 11.3  $\mu$  and  $(\text{CF}_3)_2\text{C}(\text{OF})_2$  shows a relatively stronger absorption at 11.26  $\mu$ . Infrared spectra of fluoroxy compounds have been shown to have absorption in this region.<sup>8,14</sup> Thus the infrared spectrum of this compound is reasonable for  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ .

The  $\text{F}^{19}$  nmr spectrum (Figure 2) shows an absorption at  $\phi^* -148.0$ , which is assigned to the OF groups; it is split into a sevenfold peak<sup>15</sup> by the six equivalent fluorine nuclei of the two  $\text{CF}_3$  groups. The absorption at  $\phi^* 70.1$  is a triplet assigned to the  $\text{CF}_3$  groups. The coupling constant is 14.5 cps. The peak areas were found to be in the ratio of 1.0:3.2.

Because of the extreme tendency to explode exhibited by the samples of undiluted 2,2-bis(fluoroxy)perfluoropropane prepared in this work, additional characterization of this compound was not done. Although some may feel that the structure of 2,2-bis(fluoroxy)perfluoropropane is thus tentative, it is the opinion of the authors that the identity of this compound is firmly established on the basis of straightforward analysis of the  $\text{F}^{19}$  nmr spectrum and additionally supported by the in-

(15) Although Figure 2 only shows five peaks which are observed with certainty for the OF absorption, subsequent spectra at higher concentrations clearly show sevenfold splitting for the OF absorption. The intensity ratio for the splittings also indicates that the pattern is sevenfold rather than fivefold.

frared spectrum, oxidizing properties, gas chromatography retention time, synthesis route, and identity of the other products formed.

It is well known that nuclear magnetic resonance spectroscopy is a very useful method for determining molecular structures. For fluoroxyperfluoroalkanes it should be noted that  $\text{F}^{19}$  nmr spectroscopy is an exceptionally definitive method. There are two features of the spectra of both mono- and bis(fluoroxy)perfluoroalkanes which make them particularly valuable for structure assignment. (1) The values of the chemical shift for the fluorine of a fluoroxy group lie within a narrow range (approximately  $\phi^* -140$  to  $-160$ ) and are well outside the range of most other fluorine absorptions. (2) Furthermore, the OF group as well as other types of F in fluoroxyperfluoroalkanes give unusually clear, sharp, and well-resolved spectra (although for OF compounds containing longer perfluoroalkyl chains, the resolution becomes poorer because of the many rather similar coupling constants involved). Thus, consideration of the chemical shifts together with simple first-order analysis of the fine structure caused by spin-spin interaction as well as the relative area ratios permit an unequivocal assignment of structure to the OF compound in many instances. An extensive file of nmr spectra of related compounds has aided greatly in assigning specific positions to specific groups, of course. For all fluoroxy compounds reported by us to date, additional analytical data have merely served to confirm the structure as assigned from nmr data.

Obviously, molecular weight and elemental composition data, although useful, do not distinguish between compounds having the same molecular formula. Since  $\text{F}^{19}$  nmr spectra of simple molecules such as the fluoroxyperfluoroalkanes reported by us can often yield molecular structures directly, elemental composition and molecular weight of the compound are also indirectly obtained. Moreover, nmr has the extremely valuable advantage (especially for very reactive or unstable compounds) of not requiring completely pure samples. In a number of cases, only nmr spectroscopy has allowed a definite structure determination for several new compounds having the same molecular formula.<sup>1a,9</sup>

## Experimental Section

**General Procedures.** The direct fluorination reactions were carried out by a static bed procedure similar to that described previously.<sup>3</sup> Fluorine (General Chemical Division, Allied Chemical Corp., about 95% pure), diluted with nitrogen to the desired concentration (mole per cent), was passed over the sample to be fluorinated, and the volatile products were condensed in a trap at  $-183^\circ$  from the effluent gas stream. Because fluorination reactions occasionally proceed explosively, adequate shields were provided and safety equipment was worn.

Volatile fluorination products were worked up by slightly modified standard vacuum-line techniques; contact of the fluoroxy compounds with reducing agents such as mercury and hydrocarbon vacuum grease was avoided.

Gas chromatographic analyses were carried out with a Perkin-Elmer vapor fractometer (Model 154-D), which had been equipped with 3M Co. linear-type gas sampling and backflush valves. Perfluorotributylamine<sup>16</sup> (33% on 30-60 mesh acid-washed Celite)<sup>17</sup> gave the best results of all the stationary phases examined. The column temperature was usually maintained at  $-30^\circ$ . For preparative scale separations 0.5-in. diameter columns of 10-ft and 8 ft, 7-in. length were employed. Helium, dried by passing through

(16) FC-43 (3M Co.).

(17) Chromosorb P (Johns-Manville).

4A Linde Molecular Sieves cooled in liquid nitrogen, was the carrier gas at flow rates of 150 to 320 cc/min.

red spectra were obtained on a Perkin-Elmer Model 21 beam instrument with a 2.5-cm gas cell with sodium chloride windows. Fluorine nuclear magnetic resonance spectra were obtained with a Varian V-4300-2 instrument operating at 40.0 Mc. perfluoromethane was used as an internal standard for the determination of shielding values. The shielding values are in  $\phi^{19}$  units at dilutions of about 15–30%, negative values for  $\text{CF}_3$ . All precision measurements (chemical shifts and spin-lattice relaxation times) were made according to techniques described by

Side bands were produced by amplitude modulation of the radiofrequency for reasons discussed previously.<sup>3</sup>

Measurements of  $\text{CF}_3\text{CF}(\text{OF})_2$  have been carried out for the most part by vacuum-line techniques. The course of reactions has been followed by appropriate methods such as infrared, nmr, and mass spectroscopy, powder X-ray, gas chromatography, and  $P$ - $V$ - $T$  measurements, as well as conventional volumetric analyses. Elemental analyses for carbon and fluorine were conducted according to standard microcombustion procedure for highly fluorinated compounds.<sup>11</sup> Differential thermal analyses were carried out using apparatus and procedures developed in these laboratories for highly explosive, fluorine-containing compounds.<sup>12</sup>

**Precautions.** It should be noted that the OF-containing compounds described in this paper are potentially hazardous, although they have been handled, with the exception of 2,2-bis(fluoroxy)perfluoropropane, without great difficulty. However, explosions have occurred in the course of this work, and it is recommended that suitable protective equipment<sup>13</sup> be used when pre-treating, or storing these compounds. No detailed toxicity data have been carried out on these substances, but it would be advisable to avoid exposure to any OF-containing compound of the known toxicity of  $\text{OF}_2$ .<sup>14</sup>

**Preparation of the Monosodium Salt of Perfluoroacetone Hydrate.** A sample (0.038 mole) of perfluoroacetone hydrate was added with enough 1 *N* NaOH to bring the pH to 8.8. The amount of NaOH (38 ml) was close to the stoichiometric equivalent. The aqueous solution was evaporated to dryness in air and then in vacuum at room temperature. The white, crystalline solid thus obtained was found to be soluble in ether.

Calcd for  $\text{C}_2\text{F}_5\text{HO}_2\text{Na}$ : C, 17.5; Na, 11.2. Found: C, 17.5; Na, 11.2.

Elemental analysis and infrared spectrum are consistent with the molecular formula  $(\text{CF}_3)_2\text{C}(\text{OH})\text{ONa}$ . Absorptions at 4.1 and 5.2  $\mu$  appear to be due to a strongly associated OH structure. The infrared spectrum shows practically no carbonyl-type absorption.

**Preparation of the Monosodium Salt of Perfluoroacetone Hydrate.** A sample (7.3 mmoles) of the sodium salt of perfluoroacetone hydrate was treated with 0.42 mole of fluorine under the following conditions: 3% fluorine, 1 hr,  $-20^\circ$ ; 15% fluorine, 1 hr,  $-20^\circ$ ; 3% fluorine, 4 hr, temperature gradually increased from  $-20^\circ$

to  $20^\circ$ . The residual material in the reactor was found to weigh 0.47 g. The contents of the liquid oxygen trap were worked up as follows. The noncondensable gases were removed from the trap at liquid nitrogen temperatures under vacuum, and about 0.5 ml of  $\text{CFC}_2$  was condensed into the trap. (This dilution technique was found to eliminate explosions during this part of the work-up.) The mixed condensate was then allowed to warm gradually and was passed at about 40 mm pressure through traps at  $-78^\circ$ ,  $-119^\circ$ , and  $-196^\circ$ . The  $-119^\circ$  fraction contained  $(\text{CF}_3)_2\text{CFOF}$  in major amount and  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ ,  $\text{C}_2\text{F}_5\text{OF}$ , and  $\text{CF}_3\text{CF}(\text{OF})_2$  in smaller amounts. The  $-196^\circ$  fraction also contained small amounts of the latter two compounds. Because of the large incidence of explosions in these runs, little reliable data regarding yields are available. In a run carried out before the dilution technique was used, a total of 4.05 mmoles of volatile products was isolated from 7.3 mmoles of starting material. It was estimated that 1.5 mmoles or about 35% of the isolated product consisted of OF-containing compounds. A typical product distribution was estimated by means of  $\text{F}^{19}$  nmr and infrared spectroscopy to consist of approximately 20–25%  $(\text{CF}_3)_2\text{CFOF}$ , 5%  $(\text{CF}_3)_2\text{C}(\text{OF})_2$ , 5%  $\text{C}_2\text{F}_5\text{OF}$ , and 3%  $\text{CF}_3\text{CF}(\text{OF})_2$ . The major by-products were generally  $\text{CO}_2$  and  $\text{COF}_2$ .

**Fluorination of Nitrosyl Trifluoroacetate.** Nitrosyl perfluoroacetate was kindly supplied by Dr. C. W. Taylor of our Central Research Laboratories. It was prepared by treating silver perfluoroacetate with excess nitrosyl chloride.<sup>15,16</sup> A 1-g (7.0 mmoles) sample of this compound, contained in a stainless-steel boat in the reactor, was treated with 0.16 mole of fluorine (2%) at  $-15^\circ$  over a 6-hr period. The trapped gases were fractionated on the vacuum line through traps at  $-111^\circ$  and  $-196^\circ$ . The lower boiling fraction consisted of 2.1 mmoles of products, which included  $\text{C}_2\text{F}_5\text{OF}$ . The over-all yield of this compound was 19%. Perfluoroacetyl fluoride,  $\text{COF}_2$ , and  $\text{NO}_2\text{OF}$  were the major by-products.

**1,1-Bis(fluoroxy)perfluoroethane.** 1,1-Bis(fluoroxy)perfluoroethane was purified by gas chromatography at  $-30^\circ$ . Its retention time was found to be 92 relative to fluorotrichloromethane. It is a colorless gas with an estimated boiling point of  $-35^\circ$ ; its melting point lies between  $-83^\circ$  and  $-77^\circ$ . Elemental analyses were obtained on a sample of chromatographed  $\text{CF}_3\text{CF}(\text{OF})_2$ . A molecular weight determination (vapor density) on this material gave a value of 164 (calculated 170).

Anal. Calcd for  $\text{C}_2\text{F}_6\text{O}_2$ : C, 14.1; F, 67.0. Found: C, 14.1; F, 65.5.

**2,2-Bis(fluoroxy)perfluoropropane.** 2,2-Bis(fluoroxy)perfluoropropane was purified by gas chromatography at  $-30^\circ$ . Its retention time was found to be 217 relative to fluorotrichloromethane. It is a colorless gas, which is rather prone to explode.

**Acknowledgments.** The authors are indebted to Dr. Robert L. Bohon for dta measurements, to Dr. Robert L. Rebertus for checking the stoichiometry of several reactions, and to Dr. John J. McBrady and Mr. Rudd A. Meiklejohn for their help and counsel in regard to the interpretation of the nmr spectra. We also wish to thank the Analytical Section of our Central Research Laboratories for their expert support, and Mr. Richard B. Castle and Mr. Larry A. Fletcher for their fine experimental assistance.

# Crystal and Molecular Structures of Pentacoordinated Group V Compounds. I. 2,2,2-Triisopropoxy-4,5-(2',2''-biphenyleno)-1,3,2-dioxaphospholene. Orthorhombic<sup>1,2</sup>

Walter C. Hamilton, Sam J. LaPlaca, Fausto Ramirez, and C. P. Smith

Contribution from the Departments of Chemistry, Brookhaven National Laboratory, Upton, New York 11973, and the State University of New York, Stony Brook, New York. Received December 5, 1966

**Abstract:** The reaction of triisopropyl phosphite with phenanthrenequinone forms a 1:1 adduct, 2,2,2-triisopropoxy-4,5-(2',2''-biphenyleno)-1,3,2-dioxaphospholene. This cyclic unsaturated pentaoxyphosphorane crystallizes in two allotropic forms. The preparation of these forms and the crystal structure of the orthorhombic form are described in this paper. The space group is *Pbca* with eight molecules in a cell of dimensions  $a = 18.18 \pm 0.01$  Å,  $b = 25.03 \pm 0.01$  Å, and  $c = 10.14 \pm 0.01$  Å. The phosphorus atom is at the center of a  $PO_5$  trigonal bipyramid, with two isopropoxy groups in equatorial positions and one in an apical position. The phenanthrenequinone moiety forms a bridge between one apical and one equatorial position as it forms a  $C_{10}O_2P$  five-membered ring. The apical P–O bond length in the ring is  $1.76 \pm 0.02$  Å. The apical bond length to the isopropoxy group is  $1.66 \pm 0.02$  Å. The equatorial bond lengths have an average value of 1.61 Å. The C–C bond length in the five-membered ring is considerably shorter than the corresponding bond in phenanthrene. More accurate values for the geometrical parameters were obtained for the monoclinic form, discussed in paper II of this series.

The reaction of trialkyl phosphites with *p*-quinones involves an attack by phosphorus on oxygen. The product seems to be a 1:1 dipolar adduct (I), which undergoes a very rapid alkyl group translocation to a stable alkyl ether of a *p*-quinol monoposphate (II).<sup>3</sup>

When this reaction was investigated in the series of *o*-quinones, a different and new type of structure was isolated.<sup>4</sup> The product, again, was a 1:1 adduct of the phosphite and the quinone, in which the phosphorus had attacked an oxygen atom of the latter. However, no alkyl group translocation was observed in this case. The product was formulated as a cyclic unsaturated pentaoxyphosphorane (IV), a derivative of the 1,3,2-dioxaphospholene ring system.

The oxyphosphorane structure IV was originally based on the relatively large positive shift of the  $P^{31}$  nmr signal of these adducts relative to  $H_3PO_4$ . For instance, the trimethyl phosphite adduct has  $\delta P^{31} = +44.7$  ppm, and the triphenyl phosphite adduct has  $\delta P^{31} = +58.7$  ppm. These positive P shifts, indicative of a rather effective shielding of the phosphorus nucleus by electrons, seem to favor the cyclic structure IV over the open-chain dipolar structure III. Moreover, the adducts are remarkably soluble in hexane and in benzene, a behavior not expected for dipolar structures like III. The infrared spectrum also favors the phospholene formulation IV.

More recently,<sup>5</sup> dipolar structures like V have been made from *o*-quinones and tris(dimethylamino)phosphine; they give negative P shifts; for example,  $\delta P^{31} = -38.6$  ppm for V. On the other hand, the cyclic *spirotriaminodioxaphosphoranes* (VI), made from cyclic triaminophosphines, have positive shifts;  $\delta P^{31} = +29.8$  ppm.

The behavior of  $\alpha$ -diketones,  $RCOCOR$ , toward tertiary phosphite esters was found to be analogous to the behavior of *o*-quinones. These results were reported by three independent groups of investigators.<sup>4,6,7</sup>

is paper describes the initial investigation of the al and molecular structure of the adduct made phenanthrenequinone and triisopropyl phosphite, triisopropoxy-4,5-(2',2''-biphenylene)-1,3,2-dioxapholene (VII). This adduct was obtained in crystalline forms, monoclinic and orthorhombic. discuss here the crystal structure of the orthorhombic form; the preliminary results have already reported.<sup>2</sup> The following paper<sup>3</sup> describes the ture of the monoclinic form and compares the

VII

reaction of the quinone with the phosphite was carried out in the absence of solvent. The reaction is exothermic and the heat of the reaction raised the temperature of the mixture to 120°. The melt crystallized in the monoclinic form. Recrystallization from hexane gave the monoclinic form if the crystallization was carried out very slowly and without disturbances. The adduct in hexane solution was cooled rapidly and crystallization was induced by scratching, the orthorhombic form resulted. Both forms had the same  $P^{31}$  and  $H^1$  spectra and the same infrared spectra in solutions. Crystal data for  $C_{28}H_{28}O_5P$ , mol wt 416.45, showed the orthorhombic form probable space group  $Pbca$ :  $a = 18.18 \pm 0.01$  Å,  $b = 25.03 \pm 0.01$  Å,  $c = 10.14 \pm 0.01$  Å,  $Z = 8$ ,  $\rho_{X\text{-ray}} = 1.20$  g cm<sup>-3</sup>. The monoclinic form showed probable space group  $P2_1/c$ :  $a = 25.997 \pm 0.001$  Å,  $b = 8.894 \pm 0.001$  Å,  $c = 9.880 \pm 0.001$  Å,  $\beta = 94.25 \pm 0.01^\circ$ ,  $Z = 4$ ,  $\rho_{X\text{-ray}} = 1.213$  g cm<sup>-3</sup>.

## Experimental Section

**Preparation of the Phenanthrenequinone-Triisopropyl Phosphite Adduct.** 2,2,2-Triisopropoxy-4,5-(2',2''-biphenylene)-1,3,2-dioxapholene. The quinone was recrystallized from benzene, the phosphite ester was kept over sodium wire, decanted from 1 distilled with protection against moisture. Triisopropyl phosphite (6.5 ml, 25.5 mmoles) was added to phenanthrenequinone (5.3 g, 25 mmoles) at 20°. The temperature of the mixture began to rise within 2 min; when it reached 37°, the reaction became strongly exothermic and the temperature rose 10° in 1 min. The resulting reddish brown thick oil became solid; this material proved to be the monoclinic form of the 1:1 adduct. The crystals were dissolved in 20 ml of boiling hexane. The 1:1 adduct is pale yellow, this solution was red and had traces of undissolved phenanthrenequinone; these traces of quinone can be removed by filtration, but they do not interfere in subsequent steps in the purification of the adduct. The red color seems to be due to a very deeply colored complex between the 1:1 adduct as donor and the quinone as acceptor.)

The hexane solution was allowed to cool to 20°, very slowly (12 hr) without any disturbances. The first crop of reddish crystals (60% of the theory) proved to be the monoclinic form of the adduct. The same monoclinic form is obtained by recrystallization from benzene, using 2 ml of hexane/g of adduct, provided that the solution is allowed to cool to 20° very slowly as described above. However, if cooling is rapid and if the crystallization process is disturbed, the crystals that result have the orthorhombic form. It has not been possible to obtain the monoclinic form by recrystallization of the orthorhombic crystals from benzene by slow cooling.<sup>9</sup>

The monoclinic form of the 1:1 adduct had a softening point of 97–98°, but it melted completely at 107–108° (in an open capillary tube). The orthorhombic form, made by dissolving monoclinic crystals in hexane and cooling rapidly while scratching the sides of the flask with a glass rod, had a sharp melting point of 107–108°. The  $P^{31}$  and the  $H^1$  nmr spectra of both forms were indistinguishable in  $CDCl_3$  solution. The infrared spectra of both forms in  $CCl_4$  solution were also identical.

The infrared spectrum was taken in a Perkin-Elmer Model 21 spectrometer and had the following bands (in cm<sup>-1</sup>; w, weak; m, medium; s, strong; with respect to the C–H stretching at 2960 cm<sup>-1</sup> regarded as medium): 1650 (m), 1600 (w), 1505 (w), 1455 (m), 1380 (s), 1330 (w), 1170 (m), 1135 (w), 1105 (ms), 1060 (mw); 1015 (vs), 980 (m), 890 (w), 875 (w), and 865 (w).

The  $H^1$  nmr spectrum, in  $CCl_4$  solution, was taken at 60 Mcps. The spectrum examined at a 500-cps sweep width showed an 8  $H^1$  multiplet centered at  $\tau$  2.2 (aromatic  $H^1$ ) ( $\tau$  = shift in ppm from tetramethylsilane taken as 10); the methine  $H^1$  gave a 3  $H^1$  multiplet at  $\tau$  5.40 (*vide infra*); the methyl  $H^1$  gave an 18  $H^1$  doublet,  $J_{HCH} = 6.1$  cps, centered at  $\tau$  8.75. When the spectrum was examined at a 50-cps sweep width, the methine  $H^1$  gave a doublet,  $J_{HCOF} = 8.2$  cps, of septets,  $J_{HCH} = 6.2$  cps; the methyl  $H^1$  gave a doublet,  $J_{HCOF} = 6.2$  cps, of doublets,  $J_{HCOF} = 0.7$  cps. Examination of the methine region at 100 Mcps gave the couplings,  $J_{HCOF} = 8.4$  and  $J_{HCH} = 6.4$  cps; there was no indication of further fine structure and no indication of nonequivalence of the three isopropoxy groups at 30°.

The  $P^{31}$  nmr data are summarized in Table I.

Table I

Crystalline form	Solvent	$\delta P^{31}$ , ppm vs. $H_3PO_4$
Monoclinic	Benzene	+49.2
Monoclinic	$CDCl_3$	+48.6
Monoclinic	Dimethylformamide	+49.0
Monoclinic	Benzene-methanol (1:1)	+49.2
Monoclinic	Chloroform-methanol (1:9)	+49.0
Orthorhombic	$CDCl_3$	+48.6

The adduct, in both crystalline forms, is sparingly soluble in methanol, but quite soluble in hexane, benzene, methylene chloride, carbon tetrachloride, and chloroform.

**Anal.** Calcd for  $C_{28}H_{28}O_5P$ : C, 66.4; H, 6.9; P, 7.4. Found: C, 66.0; H, 6.8; P, 7.3.

When the hexane filtrate (from which about 60% of the monoclinic form had been removed by the slow crystallization described above) was concentrated under vacuum until crystals appeared, an additional 20% of adduct resulted; this crop proved to be the orthorhombic form by X-ray examination.

## Crystal Structure Determination

A sealed vial containing orthorhombic crystals was opened in a dry nitrogen atmosphere, and single crystals suitable for X-ray photography were sealed in glass capillaries with a wall thickness of 0.01 mm. The needle-like crystals were approximately 0.2 mm in diameter and 0.4 mm long. The  $c$  axis of the crystal was in each case parallel to the capillary axis. The unit cell and space group were determined from precession and Weissenberg photographs. The systematic absences,  $h0l$  for  $l$  odd,  $0kl$  for  $k$  odd, and  $hk0$  for  $h$  odd, are consistent with the assigned space group.

Intensities of 754 reflections were visually estimated from integrated Weissenberg photographs of the  $hk0$ ,  $hk1$ ,  $hk2$ ,  $hk3$ ,  $hk4$ ,  $hk6$ , and  $hk7$  reciprocal lattice layers.

(9) This curious behavior is undoubtedly due to the presence of seeds of the orthorhombic form being present. Clearly, there can be no difference between solutions prepared from the two crystalline forms.

\* Standard deviations for x, y, and z are those obtained from the least-squares analysis as described in the text and are indicated in parentheses in terms of the least significant figure in the parameter value. The atoms are identified in Figure 1.

Structure factors were derived in the usual way by application of Lorentz and polarization factors. No absorption correction was applied; the linear absorption coefficient for Cu K $\alpha$  radiation is 12.96 cm<sup>-1</sup>. The structure was solved by location of the phosphorus atom from a three-dimensional Patterson function and by a series of difference electron density syntheses. No attempt was made to locate the hydrogen atoms.

A separate isotropic temperature factor was applied to each atom, and a series of least-squares refinements reduced the value of

$$R = \frac{\sum |F_o| - |F_c|}{\sum |F_o|}$$

to 0.13. We had hoped for better agreement at this stage of the refinement. This fact together with the fact that the estimated errors of the bond lengths in the phenanthrene ring were rather large led us to collect a complete new set of data, this time using a scintillation counter and a  $2\theta$ - $\theta$ -scan technique with the crystal mounted on a General Electric single crystal orienter.<sup>10</sup> Nickel-filtered Cu K $\alpha$  radiation was again used. Refinement of the structure based on this data set resulted in parameter values substantially the same as those obtained previously and an agreement factor R which was no better. It now seemed probable that the lack of agreement at this stage was due to the fact that the relatively large thermal motions were not being accounted for properly by the individual isotropic temperature factors. The final series of refinements was

Phenanthrene Ring							
C <sub>1</sub> -C <sub>2</sub> , 1.26 ( $\sigma = 0.04$ ); mean of 15 other C-C, 1.42 ( $\sigma = 0.05$ ); C-C-C angles, 109-132; mean, 120 ( $\sigma = 6$ )							
Isopropoxy Groups (Mean Values)							
O-C 1.47 ( $\sigma = 0.02$ )				P-O-C 128 ( $\sigma = 3$ )			
C-C 1.54 ( $\sigma = 0.04$ )				O-C-C 106 ( $\sigma = 3$ )			
				C-C-C 115 ( $\sigma = 2$ )			

\* These values are not as accurate as those for the monoclinic allotrope.<sup>6</sup> The standard deviations of P–O, O–C, and C–C distances are about 0.02, 0.03, and 0.04 Å, respectively. The standard deviations of the bond angles range from 1° for O–P–O angles to 5° for some of C–C–C angles. The atoms are labeled as in Figure 1.

factors, one for each of the Weissenberg layers and one for the counter data, were also included as parameters in the least-squares refinements. The least-squares refinement was carried out on the structure amplitudes, with the counter data being weighted by  $w = (\sigma^2 + 0.0025F^2)^{-1}$ , where  $\sigma^2$  is the estimated variance of  $F$  based on the Poisson counting statistics, and the visual photographic data by  $w = (0.01F^2)^{-1}$ , except that reflections with intensities lying below a preassigned minimum value were given constant weight. As the least-squares program used did not permit simultaneous refinement of the 269 parameters, the final refinement consisted of alternating cycles of refinement of partial parameter sets as shown in tabular form below.

Cycle	Parameters refined
N-3	Scale and 14 atoms in phenanthrene ring
N-2	15 other atoms
N-1	3 × 29 position parameters
N	6 × 29 thermal parameters

The value of  $R$  had converged at this point to 0.088 for calculated structure amplitudes based on the positional parameters in Table II and the anisotropic thermal parameters which are not quoted. The standard deviations are those estimated by the usual methods from the least-squares refinements on cycles N and N-1. These will be underestimates of the marginal standard deviations if there is any correlation between the two parameter sets refined as blocks.

A final difference Fourier synthesis,  $\rho_{\text{obsd}} - \rho_{\text{calcd}}$ , was calculated. The maximum electron density in this synthesis was 0.463 e Å<sup>-3</sup>, indicating that no atoms other than hydrogen remain to be located.

The observed and calculated structure factors are presented in Table III.

### Description of the Molecular Structure

Interesting interatomic distances and angles are presented in Table IV. These are not as accurate as those for the monoclinic form,<sup>8</sup> to which reference should be made for definitive bond lengths.

As shown in Figure 1, the phosphorus atom lies at the center of a trigonal bipyramid of the five oxygen

atoms which are covalently bound to the phosphorus. The distortions from the ideal O–P–O angles of 90 and 120° are slight. Two of the isopropoxy groups are bound to the phosphorus in equatorial positions and one in an apical position. The phenanthrenequinone

The large amplitudes of thermal motion and the size of the molecule with the attendant complexity of possible vibrations, librations, and other motions would make any detailed discussion of the thermal motion somewhat pretentious. Since the accuracy of these parameters is quite low, we have not quoted the individual values but have given only the root-mean-square displacements in Table II. There are significant anisotropies, and the amplitudes of motion are in general larger as the distance from the P atom increases.

The intermolecular packing is apparently determined entirely by interactions between carbon atoms or the hydrogens attached to them. There are six independent distances less than 4.0 Å between carbon atoms of phenanthrene groups in adjacent molecules: 3.55, 3.73, 3.77, 3.78, 3.79, 3.87. There are two such distances between carbon atoms of isopropyl groups: 3.86, 3.90. The remaining eleven distances are between phenanthrene carbon and isopropyl carbon:

3.50, 3.72, 3.72, 3.75, 3.75, 3.76, 3.89, 3.89, 3.94, 3.95, 3.97. There is nothing singular to be noted about these distances. Any detailed discussion of the intermolecular forces would require knowledge of the hydrogen-atom positions—which were not determined.

The intramolecular nonbonded distances are normal except for the four short distances between oxygen atoms and the central carbon atom of neighboring isopropyl groups. These are (in Å) O<sub>2</sub>-C<sub>31</sub>, 2.804; O<sub>1</sub>-C<sub>41</sub>, 2.695; O<sub>4</sub>-C<sub>31</sub>, 2.960; O<sub>3</sub>-C<sub>51</sub>, 2.700. This represents what must be an extreme overcrowding of the molecule, a factor which perhaps explains the relative instability of these kinds of molecules and perhaps the advantage derived from having a five-membered ring involving two of the oxygen atoms which may minimize such interactions. Intramolecular overcrowding might be, at least partially, responsible for the differences in molecular structure observed among adducts of phenanthrenequinone with tris(dialkylamino)phosphines, for example, V and VI.

## Crystal and Molecular Structures of Pentacoordinated Group V Compounds. II. 2,2,2-Triisopropoxy-4,5-(2',2''-biphenylene)-1,3,2-dioxaphospholene. Monoclinic<sup>1a</sup>

Contribution from the Chemistry Department, Brookhaven National Laboratory, Upton, New York 11973, and Philips Laboratories, Briarcliff Manor, New York. Received December 5, 1966

**Abstract:** The crystal and molecular structures of the monoclinic allotrope of the phenanthrenequinone-triisopropyl phosphite 1:1 adduct have been determined by single crystal X-ray diffraction techniques. The space group is P2<sub>1</sub>/c with four molecules in a unit cell of dimensions  $a = 25.997 \pm 0.001$  Å,  $b = 8.894 \pm 0.001$  Å,  $c = 9.880 \pm 0.001$  Å, and  $\beta = 94.25 \pm 0.01^\circ$ . The final  $R$  factor for 2183 independent reflections is 0.109. The molecular structure is a trigonal bipyramid of oxygen atoms around the phosphorus with two isopropoxy groups in equatorial positions and one in an apical position. The phenanthrenequinone moiety bridges one apical and one equatorial position, thereby forming a C<sub>2</sub>O<sub>2</sub>P five-membered ring. The apical P-O bonds show the lengthening (relative to the equatorial bonds) commonly observed in PX<sub>5</sub> structures. In addition, P-O bonds in the five-membered ring are further lengthened, an effect that can be attributed to molecular  $\pi$  bonding.

A preliminary account of the molecular and crystal structures of the phenanthrenequinone-triisopropyl phosphite 1:1 adduct (PQTP), orthorhombic form, has been given.<sup>2</sup> A fuller account of this work including details of the preparative chemistry is in paper I of this series.<sup>3</sup> This paper reports the results of a single crystal X-ray investigation of a second crystal modification of this species. Although the work reported in paper I established the molecular geometry in the compound beyond any doubt, the present study has resulted in bond lengths of much greater accuracy. The crystal data show a monoclinic form of probable space group P2<sub>1</sub>/c;  $a = 25.997 \pm 0.001$  Å,  $b = 8.894 \pm 0.001$  Å,  $c = 9.880 \pm 0.001$  Å,  $\beta = 94.25 \pm 0.01^\circ$ ,  $\rho_{X\text{-ray}} = 1.213$  g cm<sup>-3</sup>.

## Experimental Section

A suitable crystal prepared as described in I was ground into a sphere of diameter 0.432 mm and mounted in a Lindemann glass capillary; the intensities of 2817 reflections were measured on the automatic single crystal X-ray diffractometer PAILED<sup>4</sup> using monochromatized copper K $\alpha$  radiation. The following reciprocal lattice layers were investigated:  $hk0$ ,  $hk1$ ,  $hk2$ ,  $hk3$ ,  $hk4$ ,  $hk5$ ,  $hk6$ ,  $hk7$ ,  $0kl$ ,  $2kl$ ,  $3kl$ ,  $4kl$ , and  $5kl$ . Structure factors were derived in the usual way by application of Lorentz and polarization factors and an absorption correction. The absorption correction was calculated by the expression

$$A = K_0 + K_1\theta + K_2\theta^2 + K_3\theta^3$$

where the expansion coefficients  $K_i$  were obtained from a least-squares fit to values tabulated for a spherical specimen.<sup>5</sup> The observed intensities were placed on approximate absolute scales by Wilson's method<sup>6</sup> and the resulting 14 scale factors reduced to a

gle scale factor by a least-squares method.<sup>7</sup> At this point all duplicate and symmetrically equivalent reflections were averaged, yielding 2183 independent observations. The structure was solved by location of the phosphorus atom from three-dimensional Patterson function and by a series of difference

electron density syntheses. In addition, the symbolic addition method was used for an independent determination of a trial structure (see Appendix). Both methods gave the same model.

Anisotropic temperature factors for each atom and a single scale factor were used in a series of least-squares refinements. The data were first weighted by the function

$$w = (\sigma^2 + 0.0009F^2)^{-1}$$

\* Thermal parameters are those in the expression  $\exp\{-\sum_{i,j} \beta_{ij} h_i h_j\}$ . Estimated standard deviations in parentheses.

where  $\sigma$  is the estimated variance of  $F^2$  based on the Poisson counting statistics. An analysis of variance with the reflections sorted into intensity classes indicated that this weighting scheme still assigned too much weight to the more intense reflections. The final weighting scheme was chosen so that the mean value of

Figure 1. Molecular structure of phenanthrenequinone-triisopropyl phosphite 1:1 adduct. The numbering of the atoms corresponds to that in the tables and is not an official numbering.

$w\Delta(F^2)$  was independent of the intensity class. This weighting scheme resulted in substantially improved estimated standard deviations on the parameters and to a final value of

$$R = \frac{\sum |F_o| - |F_c|}{\sum |F_o|} = 0.109$$

Since the least-squares program used did not permit simultaneous refinement of the 262 parameters, the final refinement consisted of alternating cycles of refinement of partial parameter sets as shown in tabular form below.

The standard deviations on the parameters given in the next section are those estimated by the usual methods<sup>8</sup> from the least-

Cycle	Parameters refined
N-3	14 atoms in phenanthrene ring (all parameters) + scale
N-2	15 other atoms (all parameters) + scale
N-1	6 × 29 thermal parameters
N	3 × 29 position parameters + scale

squares refinements on cycles N and N-1. These will be underestimates of the marginal standard deviations if there is any correlation between the two parameter sets refined as blocks. Various considerations suggested that conservative estimates of the marginal standard deviations in the derived bond lengths and angles could be taken as 1.5 times those estimated from the least-squares refinement, and the errors for the derived functions in the following sections include this factor of 1.5. The error estimates obtained in this way for the C-C bond lengths in the isopropoxy groups are in agreement with those obtained by considering the agreement between the six such distances which should be equal.

A final difference Fourier synthesis ( $\rho_o - \rho_c$ ) was calculated. The maximum electron density in this synthesis was less than  $0.5 \text{ \AA}^{-3}$ , showing that only hydrogen atoms remained to be located. No serious attempt was made to determine the hydrogen positions.

The observed and calculated structure factors are given in Table I.

### Description of the Structure

The final positional and thermal parameters are given in Table II with the least-squares estimates of their standard deviations. A model of the molecule is shown in Figure 1.<sup>9</sup> Tables III-VI present the bond distances and angles for the monoclinic crystal. The precision and general quality of the data are better for the monoclinic form, and these should be taken in preference to those for the orthorhombic crystal as the standard values for this compound. It should be noted, however, that there are no differences between the two which the authors consider to be significant.

(8) W. C. Hamilton, "Statistics in Physical Science," The Ronald Press Co., New York, N. Y., 1964.

(9) A standard numbering system is not used. The IUC name of the compound is 2,2,2-triisopropoxy-4,5-(2',2''-biphenylene)-1,3,2-dioxaphospholene.

**Trigonal Bipyramid.** Distances and angles in the trigonal bipyramid are given in Table III. The phosphorus atom lies almost exactly at the center of the equatorial plane of the trigonal bipyramid composed of the five oxygen atoms covalently bound to the phosphorus. As the bond angles indicate, the distortions from ideal O–P–O angles of 90 and 120° are slight. Two of the isopropoxy groups are bound to phosphorus equatorial positions, and one is in an apical position. The P–O bond lengths show large differences which are well outside the limits of experimental error and which depend in a systematic way on the position of the bond in the trigonal bipyramid. Of the three bonds in the equatorial plane, that which is also in the five-membered ring is 0.057 Å longer than the average of the other two bond lengths. Similarly, the apical bond in the five-membered ring is longer than the other apical bond, which is in turn longer than the average length of the two equatorial bonds to isopropoxy oxygens. In short, the variation in bond lengths may be regarded as a superposition of two effects: the first, the tendency of apical bonds to be longer than equatorial bonds in pentacoordinated phosphorus compounds; and second, a lengthening of the bonds joining the phosphorus to the phenanthrene ring system. Possible explanations will be discussed in a following section.

**Table III.** Bond Lengths and Angles in PO<sub>5</sub> Trigonal Bipyramid

P–O bonds have been discussed. The C–C distance is short (1.33 Å), and, although a correction for thermal motion might slightly increase this apparent bond length, it seems unlikely that it is much longer than the normal C=C double-bond length of 1.33 Å. It is significantly shorter than the corresponding distance in phenanthrene itself, 1.37 Å,<sup>10</sup> and in agreement with

(10) J. Trotter, *Acta Cryst.*, **16**, 605 (1963).

the observed rather high infrared frequency of 1650 cm<sup>-1</sup> (I). This distance was also very short in the orthorhombic crystal.

**Phenanthrene Ring.** Distances and angles in the phenanthrene ring are given in Table V. The variation

		C <sub>10</sub> –C <sub>11</sub> –C <sub>13</sub>	122.5 (10)

in bond distances shows a qualitative agreement with Trotter's results; however, the large standard deviations on the bond lengths in both studies make it difficult to attach much meaning to the differences. The phenanthrene ring, the phosphorus atom, and three oxygen atoms lie nearly in a single plane. The best least-squares plane through these atoms is given by

$$16.677x + 6.4125y + 2.1108z = 7.6559$$

where *x*, *y*, and *z* are the fractional coordinates of the atoms. The maximum distance from this plane is 0.07 Å.

**Isopropoxy Groups.** Distances and angles in the isopropoxy groups are presented in Table VI and are normal.

**Table VI.** Bond Lengths and Angles in Isopropoxy Groups

**Thermal Motion.** Root-mean-square components of the thermal motion along principal axes of the vibrational ellipsoids are presented in Table VII. The errors quoted are those estimated from the least-squares refinement. A stereo view of the molecule is shown in Figure 2 in which these ellipsoids of thermal motion

Figure 2. The molecular structure of phenanthrenequinone-triisopropyl phosphite 1:1 adduct found in the monoclinic crystal. The equiprobability ellipsoids illustrate the thermal motion of the atoms. This is a stereo pair and may be viewed by a hand-held stereoscope. Note especially the large amplitudes of vibration for the end carbons of the isopropyl groups.

can be observed. In this view, the ellipsoid boundaries are drawn at 50% probability. The increased thermal motion at the extremities of the molecule is quite obvious. The motions are undoubtedly complex, and, although the accuracy here is high, no attempt will be made to give a detailed analysis of these motions.

**Molecular Packing.** A comparison of the packing in the two crystalline modifications of PQTP is shown in

2.86 Å) which must represent a severe internal overcrowding of the molecule, as in the orthorhombic form.

### Discussion of the Bonding

It has become well known, as observed in the present molecule, that apical bonds in pentacoordinated phosphorus compounds are longer and weaker than equatorial bonds.<sup>12-15</sup> Qualitative molecular orbital descriptions of the bonding in these molecules have been given by several authors,<sup>13,15,16</sup> and recent calculations on bonding in phosphorus chlorfluorides<sup>17</sup> have shown these descriptions to be reasonable. The essence of the approach is to consider the X-P-X apical bonds to be formed from three p orbitals forming the type of three-center, four-electron bond that so successfully describes the bonding in interhalogen ions and rare gas halides.<sup>15</sup> It is not necessary to invoke the use of higher energy phosphorus d orbitals. This method accounts well for the  $\sigma$  bonding in PQTP and will not be discussed further.

### $\pi$ Bonding

Cruickshank<sup>18</sup> has used the concept of  $pd-\pi$  bonding to explain observed bond lengths in tetrahedral  $XO_4^{n-}$  ions ( $X = Si, P, S, Cl$ ). He found that X-O bond lengths were consistently shorter than those predicted for single bonds by the Schomaker-Stevenson rule.<sup>19</sup> In the case of phosphorus compounds, he defines the following bond lengths as representative: P-O single bond (predicted), 1.76 Å; P-O(R), 1.62-1.63 Å; P=O (free  $PO_4^{3-}$ ), 1.4 Å. An examination of the P-O bond lengths in PQTP suggests that, if Cruickshank's approach is justified, a considerable amount of double-bond character is present in the  $PO_3$  group.

The ten oxygen 2p orbitals available for  $\pi$  bonding yield, on group-theoretical analysis assuming  $D_{3h}$  symmetry, orbitals which may be designated  $a_1' + a_2'' + 2e' + 2e''$ . Phosphorus 3d orbitals of suitable symmetry for interaction with these oxygen symmetry orbitals are  $(d_{x^2-y^2}, d_{xy})e''$  and  $(d_{xz}, d_{yz})e'$ . Although these 3d orbitals are quite diffuse in the free ion,<sup>20</sup> it is conceivable that the highly electronegative oxygen

the stereo views of Figure 3 (monoclinic) and Figure 4 (orthorhombic). Both modifications exhibit alternating layers of phenanthrene rings and isopropyl groups. In the orthorhombic crystal the phenanthrene rings occur in perpendicular pairs, while in the monoclinic case the pairs are parallel with a separation between planes of about 3.5 Å (agreeing well with Pauling's estimate of the half-thickness of an aromatic molecule of 1.85 Å<sup>11</sup>). There are four intramolecular nonbonded oxygen-carbon distances less than 3 Å (2.63, 2.70, 2.74,

Figure 3. Stereo drawing of the packing in the monoclinic crystals. Note the planar packing of pairs of phenanthrene rings.

Figure 4. Stereo drawing of the packing of the orthorhombic crystals. Note that here the phenanthrene rings are nearly perpendicular at their point of closest approach. It is also interesting to observe the pronounced separation of the crystal into alternating horizontal layers of aromatic rings and isopropyl groups. The same effect exists in the monoclinic crystal, where the layers are vertical in the drawing in Figure 3.

ligands attract charge away from the phosphorus atom, causing contraction of the 3d orbitals.

The fact that the bonds to the phenanthrenequinone ring are longer than those to the isopropoxy groups in equivalent geometric positions ( $\Delta r = 0.05$  Å for the equatorial bond and  $\Delta r = 0.11$  Å for the apical bond) may be taken as firm evidence of P-O  $\pi$ - $\pi$  bonding in these and similar compounds. In PQTP, there is the possibility of interaction of any  $\text{PO}_2$   $\pi$  system with that of the phenanthrene ring. The phenanthrene ring is a competitor for the  $\pi$ -bonding electrons of the oxygen atoms. These electrons are thus not as available for bonding to phosphorus, and the bonds to the ring thus do not show the  $\pi$ -bond-caused shortening, relative to the expected single bond distances, which is apparent for the isopropoxy groups. The apical bond to the ring has just the length of 1.76 Å suggested by Cruickshank for a P-O single bond. An apical single bond in a trigonal bipyramid would be expected to be somewhat longer; thus the  $\pi$ -bond character of this bond, although small, is not altogether zero.

### Conclusions

The accurate molecular geometry of a pentacoordinated phosphorus-oxygen compound has been given. It is found that the  $\text{PO}_2$  unit exhibits the lengthening of the apical bonds that is observed in other  $\text{PX}_5$  species; this lengthening is due to the different character of the  $\sigma$  bonding. In addition, the bonds to the isopropoxy group are shortened considerably by  $\pi$ - $\pi$  bonding between O and P. This shortening is considerably less for the bonds to the phenanthrenequinone system,

which acts as a competitor for the bonding power of the oxygen 2p $\pi$  electrons.

**Acknowledgments.** We have profited from many valuable discussions with Professor F. Ramirez whose chemical work stimulated this investigation. The assistance of Dr. Paul Goldstein in the collection of the data is gratefully acknowledged. We thank Dr. D. F. Koenig for solving the structure by the symbolic addition method.

### Appendix

**Phase Determination by the Symbolic Addition Method.<sup>21</sup>** The symbolic addition method<sup>22</sup> was used to determine signs of 362 structure factors. The distribution of magnitudes of quasi-normalized structure factors agreed well with the theoretical distribution for centrosymmetric structures. The signs of six reflections having  $E$ 's greater than 2.5 were designated by letters. (To permit later correlation with early stages of a parallel attempt to determine the structure by Patterson methods, the origin was not specified.) Symbolic phase determination was first restricted to the 92 reflections having  $E$ 's not less than 2.35 until 60 of the signs were determined in three cycles of an IBM 7094 program. The lower limit of  $E$  was then reduced to 2.00, and the symbolic signs of 139 of the 169 reflections were determined at the fourth cycle. Within two further cycles, signs of 362 of the 369 reflections having  $E$ 's not less than 1.60 were determined. After the fourth

cycle, it was clear that  $c = 0^\circ$  and  $b = 180^\circ$ . After the fifth and final cycle, it was certain that  $a = d + e$ . Thus only symbols  $d$ ,  $e$ , and  $f$  remained and could be chosen at will to fix the origin; they were all chosen equal to  $0^\circ$ . The first Fourier synthesis ( $E$  map), using 367 reflections with all  $E$ 's taken as 2.0, clearly showed

23 of the 29 nonhydrogen atoms and several more probable atoms. The subsequent difference Fourier synthesis (electron density difference map) computed from these 23 atoms revealed the remaining 6 carbon atoms as well as indicating moderate shifts in the positions of the 23 input atoms.

## Identification of Two Reduction Products of Glyoxal Bis(2-mercaptoanil)nickel. Characterization of the One-Electron Reduction Product and the Partially Hydrogenated Anion

F. Lalor,<sup>1a</sup> M. F. Hawthorne,<sup>1a,b</sup> A. H. Maki,<sup>1a</sup> K. Darlington,<sup>1a</sup> A. Davison,<sup>1c</sup> H. B. Gray,<sup>1d</sup> Z. Dori,<sup>1e</sup> and E. I. Stiefel<sup>1e,f</sup>

Contribution from the Department of Chemistry, University of California, Riverside, California. Received January 12, 1967

**Abstract:** Two different paramagnetic monoanions have been previously identified as the one-electron reduction product of glyoxal bis(2-mercaptoanil)nickel, Ni(gma). These anions result from (a) the initial borohydride reduction of Ni(gma), and (b) the sodium amalgam reduction of Ni(gma). These ions differ in their physical properties. The ion resulting from (a) has a green color, with  $\langle g \rangle = 2.051$ ,  $g_1 = 2.009$ ,  $g_2 = 2.027$ , and  $g_3 = 2.119$ , while the ion resulting from (b) is red-brown, with  $\langle g \rangle = 2.0042$ ,  $g_1 = 1.979$ ,  $g_2 = 2.006$ , and  $g_3 = 2.028$  in 2-methyltetrahydrofuran. In this communication, we demonstrate that the product from (b) is identical in its properties with the one-electron electroreduction product of Ni(gma) in dimethylformamide and, since the reduction wave is reversible, is identified as the monoanion of Ni(gma). The green anion from (a) is shown to result from hydrogen addition across the conjugated bridge and is identified as Ni(H<sub>2</sub>gma)<sup>-</sup>.

The characterization of stable, square-planar nickel complexes in unusual formal oxidation states has opened an area of discussion concerning their electronic formulation.<sup>2-5</sup> Four types of complexes have played a key role in the discussion and are shown below (I-IV).

(4) E. I. Stiefel, J. H. Waters, E. Billig, and H. B. Gray, *ibid.*, **87**, 3016 (1965). The complex referred to as Ni(gma)<sup>-</sup> in the esr work in this communication is probably Ni(H<sub>2</sub>gma)<sup>-</sup>.

(5) A. H. Maki, T. E. Berry, A. Davison, R. H. Holm, and A. L. Balch, *ibid.*, **88**, 1080 (1966).

As an example of the problem, the paramagnetic ( $S = 1/2$ ) Ni(mnt)<sub>2</sub><sup>-</sup> complex has been described in two different ways: as an effectively d<sup>7</sup> Ni(III) complex, [Ni<sup>III</sup>(mnt)<sub>2</sub>]<sup>4-</sup>,<sup>2-5</sup> and as an effectively d<sup>8</sup> Ni(II)-stabilized radical ligand [Ni(II) srl] system, [Ni<sup>II</sup>(mnt)<sub>2</sub>]<sup>3-</sup>.<sup>2,4</sup>

In many cases the same polarographic and esr results have been interpreted as supporting the Ni(III) or the Ni(II) srl picture, depending on the relative emphasis placed on various details of these experiments. A particularly unfortunate controversy has arisen concerning the interpretation of polarographic and esr experiments on various reduction products of Ni(gma).<sup>4,6</sup> Specifically, the borohydride<sup>4</sup> and sodium amalgam<sup>6</sup> reduction products are clearly different, and this has led to considerable confusion about the identity of the authentic Ni(gma)<sup>-</sup> complex. We have now thoroughly characterized the monoanionic borohydride reduction product of Ni(gma) as a partially hydrogenated species designated Ni(H<sub>2</sub>gma)<sup>-</sup> (V).

On the other hand, the sodium amalgam reduction product of Ni(gma)<sup>6</sup> has been shown to be the actual anion, Ni(gma)<sup>-</sup>. These results should give added impetus to the total resolution of the outstanding problems.

It is also our view that in a number of situations the Ni(III) and Ni(II) srl descriptions approach each other. On careful examination of the allegedly opposed formulations,<sup>4,6</sup> it is apparent that there is no significant basis for controversy. Therefore, it is the purpose of this paper to present the characterization of the Ni(H<sub>2</sub>gma)<sup>-</sup>

$\text{Ni(gma)}^-$  complexes and to attempt to resolve as of the controversial electronic structural issues as e.

## mental Section

ration of  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  from  $(n\text{-Bu}_4\text{N})(\text{BH}_4)$  and  $\text{Ni}$ . All solvents used in this synthesis were degassed by four freezing and drying on the high-vacuum line unless noted e. All operations were conducted in the drybox in a dry atmosphere. Ethanol used was USP Grade Absolute. F was dried (prior to degassing) by distilling from  $\text{LiAlH}_4$ .

suspended  $\text{Ni(gma)}$ , (0.8 g, 0.0024 mole) in 150 ml of THF, solution of  $(n\text{-Bu}_4\text{N})(\text{BH}_4)$  (1.4 g, 0.0054 mole) in 50 ml of is added. The  $\text{Ni(gma)}$  rapidly dissolved, giving a green

A sample withdrawn at this stage in a flat quartz cell measurement revealed the presence of two signals. The had  $\langle g \rangle = 2.004$ , while the other had  $\langle g \rangle = 2.048$ . These were observed to decay in intensity while in the spectrometer esr measurement was made initially before the decay was l. Comparison with the signal intensity of a standard  $[\text{Ni(mnt)}]$  solution revealed that the spin concentration in the als could account only for about 6% of the Ni atoms in the solution. A second sample withdrawn from the reaction after 0.5 hr of stirring showed no trace of esr absorption = 2.

tion of 1.0 g of  $(n\text{-Bu}_4\text{N})\text{Br}$  in 150 ml of absolute EtOH ed, resulting in an immediate discharge of the green color solution of gas. A sample of the grayish black solution no esr absorption. We next bubbled a small quantity of nto the solution. A brilliant green color was observed immediately and increased in intensity as more  $\text{O}_2$  was Monitoring the solution with esr indicated that the formae green color was associated with the development of an gmal with  $\langle g \rangle = 2.047$ . An intensity measurement gave the of spins in the line equivalent to  $81 \pm 10\%$  of the number oms in the reaction mixture. Addition of excess  $\text{O}_2$  to a rtion of the reaction mixture resulted in a decrease in the of the line at  $\langle g \rangle = 2.047$  and the development of a new  $\langle g \rangle = 2.0043$ .

microcrystalline  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  was obtained by ing the  $\text{O}_2$ -treated mixture to about half its volume and with a large volume of  $n$ -hexane (Matheson Coleman and troquality, not degassed). The precipitate was washed ne and dried *in vacuo* over  $\text{P}_2\text{O}_5$ . The infrared spectrum lid was recorded as mulls in Nujol and Fluorolube.

l acceptable analyses on samples from different prepara-  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  were obtained. The best analysis ere.

Calcd for  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$ : C, 62.81; H, 8.45; S, 11.18. Found: C, 62.56; H, 8.56; N, 7.25; S, 11.10. tion of  $(n\text{-Bu}_4\text{H})[\text{Ni}(\text{HDgma})]$  from  $(n\text{-Bu}_4\text{N})(\text{BD}_4)$  and

We prepared the complex as described above, using  $(\text{BD}_4)$  instead of  $(n\text{-Bu}_4\text{N})(\text{BH}_4)$ . An infrared spectrum  $[\text{Ni}(\text{HDgma})]$  as a Fluorolube mull when compared t of  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  prepared with  $(n\text{-Bu}_4\text{N})(\text{BH}_4)$  the absence of one of the weak C-H stretching bands  $\text{cm}^{-1}$ ) and the presence of a new band at  $2130 \text{ cm}^{-1}$  ble to C-D stretching indicating the incorporation of at D atom into the gma structure. Neither sample showed ce of a band attributable to an N-H stretching vibration. ple of  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{HDgma})]$  prepared with  $(n\text{-Bu}_4\text{N})$ -s completely burned in  $\text{O}_2$ , the water of combustion was and frozen, all volatiles were pumped off *in vacuo*, and the as introduced into a mass spectrometer. The ratio of ghts  $\text{HOD}/\text{H}_2\text{O}$  was determined. The calculated ratio l for natural abundance of D) for one D atom/mole is 1 for two D atoms/mole is 0.088. Two successive deter- yielded 0.043 and 0.044, establishing unequivocally that tion of  $\text{Ni(gma)}$  with  $\text{BD}_4^-$  involves the incorporation of rium atom per molecule of  $\text{Ni(gma)}$ .

tion of  $(n\text{-Bu}_4\text{N})[\text{Ni(gma)}]$ . All solvents were dried and as described in an earlier section, and all operations were ut in a drybox.

) (3.29 g, 0.01 mole) was suspended in 50 ml of THF and ith 0.20 g (0.0087 g-atom) of sodium in 20 ml of Hg. lex dissolved rapidly on shaking to form a deep red- ution.

Addition of 3.22 g of  $(n\text{-Bu}_4\text{N})\text{Br}$  in 100 ml of ethanol to the filtered solution gave a brown crystalline precipitate which was filtered and dried *in vacuo* over  $\text{P}_2\text{O}_5$ . The  $(n\text{-Bu}_4\text{N})[\text{Ni(gma)}]$  is extremely air sensitive and must be handled in an inert atmosphere.

Anal. Calcd for  $(n\text{-Bu}_4\text{N})[\text{Ni(gma)}]$ : C, 63.05; H, 8.11; N, 7.35; S, 11.22. Found: C, 61.93, 61.83; H, 7.65, 7.83; N, 7.22, 7.07; S, 11.36, 11.55.

Physical Measurements. Static susceptibility measurements on solid samples were made at room temperature by the Gouy method using  $\text{Hg}[\text{Co}(\text{SCN})_4]$  as calibrant.<sup>6</sup> Conductances were determined on an Industrial Instruments bridge, Model RC16B2, using a cell calibrated with 0.02 M KCl solution. Polarographic measurements were made in DMF solution with a dme in a three-electrode cell, using an electronic polarograph described elsewhere.<sup>7</sup> Silver-silver perchlorate was used as the reference electrode ( $\text{Ag}|\text{AgClO}_4$ , 0.1 M;  $(n\text{-Pr}_4\text{N})\text{ClO}_4$ , 0.1 M). Solutions were approximately  $10^{-3}$  M in complex and  $10^{-1}$  M in  $(n\text{-Pr}_4\text{N})\text{ClO}_4$ . Cyclic voltammetry was employed, using a platinum indicator electrode and a  $\text{Ag}|\text{AgCl}(1.0 \text{ M KCl})$  reference electrode. The same electrodes and scan rates were used for all comparative measurements. The DMF solvent for cyclic voltammetry and epr measurements was Baker Analyzed reagent, gc-spectrophotometric quality that had been fractionated under vacuum from  $\text{K}_2\text{CO}_3$  on a spinning-band column and stored in the drybox until used. Sample preparation, cyclic voltammetry measurements, and the filling of epr sample cells were all done within the drybox. Solutions were about  $10^{-1}$  M in  $n\text{-Bu}_4\text{NClO}_4$  and  $5 \times 10^{-4}$  M in complex unless otherwise stated. Optical spectra were measured on a Cary Model 14 spectrophotometer in the wavelength range 350–700 m $\mu$ . Esr measurements were made on a Varian V-4502-12 spectrometer system operating at 9500 Mc/sec using 100-kc/sec field modulation. The microwave frequency was measured by means of a Hewlett-Packard Model 2590A frequency converter and Model 5245L frequency counter. The magnetic field was monitored with a proton resonance gaussmeter whose frequency was measured by the same frequency counter.  $\langle g \rangle$  values were calculated by means of the equation<sup>8</sup>

$$g = 3.041997 \times 10^{-3} \nu_d / \nu_p$$

## Results

The green crystalline  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  complex is a 1:1 electrolyte in nitromethane ( $\Lambda = 64$ ). The esr spectrum of a polycrystalline sample of  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  shows three  $g$  values. The average  $\langle g \rangle$  estimated from the polycrystalline spectrum is  $2.050 \pm 0.005$ . The esr spectra in various carefully prepared solutions (under oxygen-free nitrogen from freshly distilled and degassed solvents), with DMF, DMSO, and THF as solvents, show  $\langle g \rangle$  values in a small range near 2.051, with the lowest vaue being  $2.048 \pm 0.002$  in THF solution. The complex has a magnetic moment of 1.95 BM in the solid state, in good agreement with the  $\langle g \rangle$  value of 2.050 from the esr spectrum of a polycrystalline sample. In DMF- $\text{CHCl}_3$  the  $\text{Ni}(\text{H}_2\text{gma})^-$  ion has the following  $g$  values in the low-temperature glass:<sup>9</sup>  $g_1 = 2.009$ ,  $g_2 = 2.027$ ,  $g_3 = 2.119$ . The  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  complex in DMF solution shows a reversible one-electron oxidation wave at  $-0.758 \text{ v}$  and a reversible one-electron reduction wave at  $-1.591 \text{ v}$  vs.  $\text{Ag}|\text{AgClO}_4$ . Under identical solvent and instrumental conditions, a pure sample of neutral  $\text{Ni(gma)}$  shows reversible one-electron reduction waves at  $-0.823$  and  $-1.605 \text{ v}$ . These differences in half-wave potentials for the  $\text{Ni(gma)}$  and  $\text{Ni}(\text{H}_2\text{gma})^-$  systems are small, but are definitely outside of experimental error.

The  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  complex is air sensitive (as would be expected from the polarographic results), and all operations which preserve its properties must be carried out under nitrogen. Upon exposure to air in any solvent the green color rapidly fades and a brown color develops. The compound is apparently being oxidized by air, but a pure sample of either  $\text{Ni}(\text{H}_2\text{gma})$  or  $\text{Ni}(\text{gma})$  could not be isolated by this route. A freshly prepared sample of analytically pure  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  was dissolved in freshly distilled THF under  $\text{N}_2$ , giving a single strong signal at  $\langle g \rangle = 2.048$ . The sample was then allowed to stand in air until it appeared brownish. The signal at  $\langle g \rangle = 2.048$  was still present but with greatly reduced intensity. In addition, a new and strong signal appeared at 2.004. An analogous experiment was then performed in DMF solution in the polarographic cell. After the brown color appeared, no reversible waves could be found, even when the cell was refushed with nitrogen. The nature of the reaction product with  $\langle g \rangle = 2.004$  is still uncertain. This paramagnetic species is not the same as  $\text{Ni}(\text{gma})^-$ , resulting from the coulometric reduction of  $\text{Ni}(\text{gma})$ , although its  $\langle g \rangle$  value is similar (*vide infra*).

Further confirmation of the identity of  $\text{Ni}(\text{H}_2\text{gma})^-$  is provided by preliminary work on the crystal structure of the borohydride reduction product of dimethylglyoxal bis(2-mercaptoanil)nickel. It is found that the  $\text{CH}_2\text{-C-C-CH}_3$  angles are consistent with a tetrahedral configuration around at least one of the carbon atoms in the bridge.<sup>9</sup>

Cyclic voltammetry measurements of  $\text{Ni}(\text{gma})$  in DMF gave a one-electron reduction wave (checked by coulometry) with a peak potential of  $-0.322$  v and an oxidation peak at  $-0.253$  v *vs.*  $\text{Ag}|\text{AgCl}$  on the reverse scan. The accuracy of these and subsequent values is estimated at  $\pm 0.003$ , unless otherwise stated, and was obtained as the average of two successive scans. Complete coulometric reduction of this solution was carried out at a constant potential of  $-0.5$  v. Cyclic scans of this solution showed a reduction peak at  $-0.320$  v and an oxidation peak at  $-0.250$  v *vs.*  $\text{Ag}|\text{AgCl}$ . This agreement of potentials leaves little doubt that the product of this electroreduction of  $\text{Ni}(\text{gma})$  is  $\text{Ni}(\text{gma})^-$ . Cyclic voltammetry measurements on the sodium amalgam reduction product of  $\text{Ni}(\text{gma})^6$  (as the analyzed  $n\text{-Bu}_4\text{N}^+$  salt) showed a reduction peak at  $-0.321$  v and an oxidation peak at  $-0.250$  v *vs.*  $\text{Ag}|\text{AgCl}$  in excellent agreement with  $\text{Ni}(\text{gma})$  and  $\text{Ni}(\text{gma})^-$  prepared by coulometric reduction. Cyclic voltammetry of  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{H}_2\text{gma})]$  showed a reduction peak at  $-0.226$  v and an oxidation peak at  $-0.146$  v *vs.*  $\text{Ag}|\text{AgCl}$ . These potentials are well outside of experimental error of the  $\text{Ni}(\text{gma})$  potentials, as are the polarographic half-wave potentials reported above.

The second reduction peaks of  $\text{Ni}(\text{gma})$  and  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{gma})]$  (sodium amalgam reduced) were also compared by sweeping both reduction peaks in the same scan. The second reduction and oxidation peaks occurred at  $-1.112$  and  $-1.031$  v for  $\text{Ni}(\text{gma})$ , and  $-1.097$  and  $-1.036$  v *vs.*  $\text{Ag}|\text{AgCl}$  for  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{gma})]$ . The estimated accuracy in this case is  $\pm 0.005$  v because of the larger voltage scan. These solutions were about  $3 \times 10^{-3}$  M in complex.

In order further to confirm the identity of the sodium amalgam reduced  $\text{Ni}(\text{gma})$  and coulometrically gener-

ated  $\text{Ni}(\text{gma})^-$ , we have made an accurate comparison of the  $\langle g \rangle$  values of the two paramagnetic ions in DMF. The coulometrically reduced  $\text{Ni}(\text{gma})^-$  solution contained  $0.1$  M  $(n\text{-Bu}_4\text{N})\text{ClO}_4$  as supporting electrolyte. In order to avoid possible ionic strength effects on  $\langle g \rangle$  values, the solution of the sodium amalgam reduced salt was also made up to  $0.1$  M in  $(n\text{-Bu}_4\text{N})\text{ClO}_4$ . With samples having  $\langle g \rangle$  near the free spin value, the utmost precision must be employed to use this quantity as a qualitative analytical tool. This is because the region near  $\langle g \rangle = 2.0023$  is thoroughly uncharacteristic, a large number of paramagnetic systems, including almost all of those described as free radicals, falling into this region. The principal uncertainty in our determination of absolute  $\langle g \rangle$  values results from the difference in magnetic field at the sample and at the proton resonance probe, which must necessarily be placed in a different region of the magnetic pole gap. In order to avoid this error, we chose to measure the difference in  $\langle g \rangle$  values of the two samples. Each sample was placed in a separate Varian flat cell, and the  $\langle g \rangle$  value of each determined in turn in the same rectangular microwave cavity. The locations of the cavity and proton probe were disturbed as little as possible between the pair of determinations. The magnetic field was left on during a pair of determinations to avoid the small error due to a change in the field difference between sample and proton probe locations which is known to occur if the magnetic field is disturbed.<sup>8</sup> Six pairs of determinations were made over a period of 3 days. In three of these the sample cells were exchanged to avoid any possible systematic error arising from this source.

The  $\langle g \rangle$  values obtained from the six determinations were  $2.004025 \pm 0.000012$  for coulometrically reduced  $\text{Ni}(\text{gma})$  and  $2.004052 \pm 0.000012$  for sodium amalgam reduced  $\text{Ni}(\text{gma})$ . It should be emphasized that these  $\langle g \rangle$  values are not known absolutely to the precision quoted above, since no correction has been made for the systematic field difference between sample and proton probe locations. The estimate of precision applies when the two values are compared. We conclude that we cannot distinguish between the  $\langle g \rangle$  values of the two samples within the precision of the determination. An evaluation of the absolute  $\langle g \rangle$  value of both samples gives  $\langle g \rangle = 2.0041 \pm 0.0001$ . We previously reported<sup>5</sup>  $\langle g \rangle = 2.0527$  for coulometrically reduced  $\text{Ni}(\text{gma})$  in  $\text{CHCl}_3\text{-DMF}$ . We now believe that the radical generated in this experiment resulted from a reaction product of  $\text{Ni}(\text{gma})$  with impurities present in DMF; the radical is possibly III or V. This result emphasizes the extreme care which must be exercised when working with these systems. Scrupulously purified DMF leads only to  $\text{Ni}(\text{gma})^-$  on electroreduction, as reported above.<sup>10</sup>

Optical absorption spectra of coulometrically reduced and sodium amalgam reduced  $\text{Ni}(\text{gma})$  in DMF were identical in the observed region,  $350\text{--}700$  m $\mu$ . Concentrations were about  $10^{-4}$  M. Extinction coefficients were not measured. The main features of both spectra in this wavelength region are a strong absorption at  $444$  m $\mu$  which has three weak shoulders at  $483$ ,  $503$ , and  $539$  m $\mu$ . A second, weaker absorption occurs at  $589$  m $\mu$ .

(10) Although  $\text{Ni}(\text{gma})^-$  is stable for at least a week in scrupulously purified DMF, it undergoes decomposition within 5 days in the impure solvent leading to three new esr signals as reported in ref 5.

On the basis of the voltammetric measurements, esr, and the similarity of the optical spectra, we conclude that the sodium amalgam reduced  $\text{Ni(gma)}^-$  is correctly identified as  $\text{Ni(gma)}^-$ .

## Discussion

**A Possible Reaction Sequence for the Synthesis of  $\text{Ni(H}_2\text{gma)}^-$ .** The data presented above show that borohydride reduction of  $\text{Ni(gma)}$  followed by treatment with a protic solvent and partial air oxidation leads to a substantial yield of the green complex designated as  $\text{Ni(H}_2\text{gma)}^-$ , an anion in which the bridge is partially saturated. Substitution of borodeuteride in the reaction gives a product which must be formulated as  $\text{Ni(HDgma)}^-$ . The infrared spectral evidence favors a C-D bond. A reaction sequence which is consistent with all of our observations may be formulated as shown in eq 1-4.

**Ground-State Electronic Structure.** One of the most interesting and desirable features to know in the mono-anionic complexes such as  $\text{Ni(mnt)}_2^-$  and  $\text{Ni(gma)}^-$  is the distribution of the unpaired electron between the metal and the ligand atoms. The  $\text{Ni(II)}$  srl and  $\text{Ni(III)}$  electronic structural formalisms imply different distributions for this unpaired electron. In the former case the unpaired electron is assumed to be in a molecular orbital of predominantly ligand composition, but metal d orbital participation is an important, if secondary, feature.<sup>3,4</sup> That is, the term " $\text{Ni(II)}$  stabilized" is meant to imply specific d orbital involvement in the appropriate molecular orbital, even though the ligands dominate in the electron distribution. The second point of view has been traditional when trying to describe the electron paramagnetic properties of "covalent" transition metal complexes. It begins from an appropriate d-orbital configuration on the metal and subsequently allows for mixing of metal and ligand orbitals of the appropriate symmetry. It is clear that properties of paramagnetic transition metal complexes

which depend upon the electron spin density near the metal atom (such as electron-metal nucleus hyperfine interaction, as well as large deviations of the  $g$  tensor from that of the free electron spin) are better handled from this point of view. The two viewpoints are, of course, complementary and fuse together in those complexes having roughly an equal distribution of spin density between metal and ligand orbitals.

Electron paramagnetic resonance should be of perhaps the greatest use in helping to decide matters of electron spin distribution in paramagnetic  $S = 1/2$  complexes such as I-V. Particularly helpful would be the measurement of the anisotropic dipole-dipole contribution to the electron-metal nucleus hyperfine tensor. Since this property depends mostly on the ground state electron configuration, and to a much smaller extent on admixture of excited configurations through spin-orbit coupling (unless the  $g$  anisotropy is very large), it is most *directly* indicative of the wave function of the half-filled orbital in a molecular orbital description. The  $g$  tensor, on the other hand, depends not only on the ground-state configurational wave function, but on all the excited configurational wave functions and their degree of admixture by spin-orbit coupling. Measurement of the  $g$ -tensor is thus not as *directly useful* in leading to a quantitative description of the half-filled orbital, within the framework of existing molecular theory.

In the series of complexes under discussion, metal nucleus-electron hyperfine interaction thus far only has been measured for I,  $\text{R} = \text{CN}$ , using a sample enriched in  $^{61}\text{Ni}$ . The hyperfine tensor was interpreted to result from a ground-state configuration in which the half-filled  $b_{3g}$  orbital was approximately 50% delocalized over the ligand  $\pi$  system.<sup>2,11</sup> This interpretation places  $\text{Ni(mnt)}_2^-$  directly in the overlap region between the two extreme descriptions (*vide supra*) of these complexes.

Care should be exercised in interpreting the  $g$ -tensor anisotropy in terms of the lowest energy configuration. This can be done only in the roughest, most qualitative way in this series of square-planar Ni complexes in the absence of detailed calculations and an adequate theory. Perhaps all that can be done at present is to define the behavior of the magnetic properties of the complex in the two extreme limits. In the limit of the  $d^7$  model,  $\text{Ni(III)}$ , we would expect a metal nucleus-electron hyperfine tensor which is consistent with the value of  $r^{-3}$  given by a calculation on a properly self-consistent metal d orbital. In the limit of the  $\text{Ni(II)}$  srl model we would expect a very small anisotropy of the metal hyperfine tensor, as well as a  $g$  tensor which approaches that characteristic of the isolated ligand free radical.

**Acknowledgment.** We wish to thank Dr. Donald Young for mass spectral analyses. This project was partially supported by grants from the National Science Foundation (GP-3398, GP-4922, and GT623-IX).

# Proton Magnetic Resonance Studies of High-Spin Nickel(II) Complexes with Pentadentate Schiff Bases

Gerd N. La Mar and L. Sacconi

Contribution from the Physical Chemistry Institute, Swiss Federal Institute of Technology, Zurich, Switzerland, and Institute of General and Inorganic Chemistry, University of Florence, Florence, Italy. Received November 21, 1966

**Abstract:** The proton magnetic resonance spectra of two series of high-spin, five-coordinated nickel(II) complexes have been observed, where the pentadentate ligand is formed from substituted salicylaldehydes and bis(3-amino-propyl)amine or bis(3-aminopropyl)methylamine. Two sets of aromatic peaks are observed, which are interpreted as arising from the nonequivalence of the two aromatic fragments in the chelate. This extent of nonequivalence is found to depend markedly on the amino-nitrogen substituent, the solvent, and the temperature. This variable magnetic nonequivalence is related to small changes in the solution structure produced by steric effects of the amino-methyl group, with the extent of nonequivalence increasing as the structure tends toward a square pyramid with the salicylaldehyde fragments bonded *cis* to each other. This tendency for these pentadentate ligands to take up a square structure with *cis* rather than *trans* aromatic rings is also evidenced for the pyridine solutions of the chelates, where some peak splitting is observed in spite of octahedral coordination. The shift patterns for the five-coordinated chelates indicate  $\pi$  delocalization, but other factors must be important. The shift distribution for the pyridine adducts is consistent with that of other related octahedral complexes.

Complexes of the pentadentate ligand of structure A have recently been shown<sup>1</sup> to produce five-coordinated 3d metal(II) complexes. Five coordination

in these high-spin nickel(II) complexes has been established<sup>1,2</sup> only very recently, though some uncharacterized complexes of this ligand has been reported earlier.<sup>3</sup> To date there are only a few documented examples of five-coordinated nickel(II).<sup>4-7</sup>

The five coordination has been established on the basis of absorption and reflectance spectra,<sup>1</sup> which are inconsistent with either octahedral or tetrahedral coordination, but closely resemble the spectra of  $[5\text{-Cl-SALen}(\text{C}_2\text{H}_5)_2\text{Ni}^{II}]$  and  $[\text{N-CH}_2\text{-SAL}]_2\text{Ni}^{II}$  in the lattice of its zinc analog, both of which have been shown to be five coordinated by X-ray analysis, the former in a distorted square pyramid<sup>8</sup> and the latter in a trigonal bipyramid.<sup>4</sup> The present complexes also form adducts with a single molecule of pyridine,<sup>1</sup> resulting in octahedral coordination, and molecular weight measurements reveal that there exist only discrete monomers in solution.

Results for a single crystal X-ray analysis on one of these complexes, NiSAL-MeDPT, carried out simul-

taneously with this work,<sup>2</sup> have proved five coordination, with a distorted trigonal bipyramidal arrangement of the five bonding atoms as shown in Figure 1. The great similarity of the reflectance and the solution absorption spectra indicates that the solution structure is essentially identical with that in the crystal.<sup>1</sup>

Proton magnetic resonance studies have proved extremely useful in elucidating various magnetic and structural properties of nickel(II) complexes in solution.<sup>9-12</sup> In view of the novel structure of these complexes, a pmr investigation was undertaken in order to determine what properties of the observed isotropic shifts can be related to their structure.

These complexes are fully paramagnetic,<sup>1</sup>  $\mu_{\text{eff}} = \sim 3.34$  BM, and give no evidence of any paramagnetic  $\rightleftharpoons$  diamagnetic equilibrium in solution. Their solution pmr spectra can thus be expected to display large, isotropic resonance shifts<sup>9,10,14</sup> for the protons from their position in the free ligand or diamagnetic zinc complex. Such shifts arise either from a proton-electron dipolar interaction or from the contact interaction resulting from the delocalization of unpaired spin onto the ligand.<sup>14</sup> The character of the observed shifts can thus depend on both the magnetic anisotropy and on the type of orbital containing the unpaired electron. Such investigations for tetrahedral nickel complexes with substituted salicylaldehydes have demonstrated<sup>15</sup> that their observed shifts originate in a contact interaction with spin in the highest filled ligand  $\pi$  orbital. From the temperature dependence of the shifts, the square-planar  $\rightleftharpoons$  tetrahedral solution equilib-

X-Ray structure for coordinating atoms in NiSAL-

as characterized,<sup>15</sup> as originally performed for oponeimines.<sup>9,16</sup> More recently, pmr investigations have been extended to nickel chelates with N-ted salicylaldimines, where the substituent is a site capable of bonding to the metal.<sup>12,13</sup> helates resulted in a complicated mixture of in solution, either octahedral, tetrahedral, and planar<sup>12</sup> or octahedral, five-coordinated, and planar.<sup>13</sup> The isotropic shift patterns for the *ral*<sup>12,13</sup> complexes differed significantly from observed for the tetrahedral species,<sup>15</sup> and the exact of the shifts is still in question, though  $\pi$  bonding is to be primarily responsible for the spin delocali-

For the chelates giving rise to five-coordinated in solution, as implied by their absorption spectra character of the observed shifts could not be related to the presence of the five-coordinated presumably because of the rapid equilibrium averaged over the shifts of the contributing species.

Report here the pmr spectra of two series of compounds with ligand A, where X = Cl, H, CH<sub>3</sub>, the two differing in the R substituent. Those with R = H designated X-NiSAL-DPT, while those with R = CH<sub>3</sub> labeled X-NiSAL-MeDPT.

## Experimental Section

Nuclear magnetic resonance spectra were recorded on a Varian spectrometer, using tetramethylsilane as internal reference. Spectra were run at 27°, unless noted otherwise. The spectra were obtained in both deuteriochloroform and pentamethylsilane, at concentrations approximately 0.05 M, with the solvent to be concentration independent. The pmr spectra of NiSAL-DPT and NiSAL-MeDPT, and their two methyl ring derivatives, were run over the temperature range -62 to +20°C, using a dewar probe and a liquid nitrogen cryostat bed elsewhere.<sup>13</sup> The pmr spectra of 0.10 M CHCl<sub>3</sub> of NiSAL-DPT and NiSAL-MeDPT were recorded as a solution of added deuteriopyridine. The diamagnetic zinc complexes were run on a Varian A-100 spectrometer.<sup>17</sup> The pmr spectra of 5-CH<sub>3</sub>-NiSAL-MeDPT and 3-CH<sub>3</sub>-NiSAL-MeDPT were also recorded in the following protonless or fully deuterated solvents: carbon disulfide, carbon tetrachloride, *d*<sub>6</sub>-benzene, *d*<sub>4</sub>-methanol, *d*<sub>5</sub>-nitromethane, and *d*<sub>3</sub>-acetonitrile. The complexes were only sparingly soluble in these solvents, 0.1 M, with the exception of CS<sub>2</sub>. All other samples were insoluble to produce discernible spectra in more than 10 solvents, often in none, or produced cloudy solutions, which precipitated within a few hours. Their pmr spectra were characterized by broad, unidentifiable peaks. Only the pmr spectra reported here for which we are reasonably certain that no position occurred. A few of the solutions were too dilute to give recognizable peaks on the DP-60 spectrometer and were

Figure 2. Pmr traces for (A) ZnSAL-MeDPT and (B) ZnSAL-DPT in CDCl<sub>3</sub>.

Figure 3. Pmr traces for ring protons of (A) NiSAL-DPT, (B) NiSAL-MeDPT, and (C) 5-Cl-NiSAL-MeDPT in CDCl<sub>3</sub>.

thus run on the more sensitive HR-100 Varian spectrometer. A few test runs on both spectrometers verified that the observed shifts are proportional to field strength.

All shifts are reported as isotropic shifts, in cycles per second at 60 Mcps, defined as the difference in resonance position for a given proton in the paramagnetic chelate and the diamagnetic zinc complex, such that upfield shifts are considered positive.

The complexes used are those reported elsewhere.<sup>1</sup> The deuterated solvents were purchased from Fluka, AG, Buchs, Switzerland, except for *d*<sub>5</sub>-nitromethane, *d*<sub>3</sub>-acetonitrile, and *d*<sub>4</sub>-methanol, which were obtained from E. Merck, Darmstadt, Germany.

An attempt was made to observe the electron spin resonance spectrum of a 0.1% solid solution of NiSAL-MeDPT in ZnSAL-MeDPT, using a Hilgher & Watts X-Band spectrometer, in order to estimate the *g*-tensor anisotropy. However, no signal attributable to the sample was located down to liquid-nitrogen temperature.

## Results

The pmr traces for ZnSAL-DPT and ZnSAL-MeDPT in *d*-chloroform are shown in Figure 2. The isotropic shifts for the ring protons of the complexes in *d*-chloroform are listed in Table I, and in Table II for the *d*<sub>5</sub>-pyridine solutions. In both cases, the peaks are referenced against the zinc complexes. The pmr traces between -2000 and +1000 cps from TMS, the region over which all aromatic ring protons are observed, are recorded in Figure 3 for *d*-chloroform solu-

azomethine proton peak taken as 2. For ZnSAL-MeDPT, these four peaks arise from the 12 methylene protons, while the amino proton is apparently included in the farthest upfield peak in this set for ZnSAL-

$\gamma$ -CH's, on the basis that a triplet appears for the MeDPT case due to coupling with the  $\beta$ -CH's, while this peak is further split by coupling to the NH proton for the DPT complex. The peak at  $-1.9$  ppm is assigned

Figure 5. Plot of ring proton chemical shifts vs. excess molar equiv of deuteropyridine for NiSAL-DPT (●) and NiSAL-MeDPT (○) in  $\text{CDCl}_3$ .

to the  $\beta$ -CH's, as it appears as a slightly broadened quintuplet indicating more or less equal coupling to the  $\alpha$ -CH's and  $\gamma$ -CH's. This peak is again more complicated in ZnSAL-DPT, presumably because of further coupling with the NH. The two smaller peaks at  $-2.4$  and  $-4.4$  ppm thus belong to the  $\alpha$ -CH's, since their multiplet structure is least affected by the amino nitrogen substituent. As this group of protons lie closest to the aromatic ring, the chemical shift difference for the axial and equatorial protons would be expected to be greatest,<sup>18</sup> the observed difference being 2.0 ppm. The multiplet structure for the  $\alpha$ -CH's in ZnSAL-MeDPT shows five components, with intensities 1:2:2:2:1. This is interpreted as arising from axial-equatorial coupling of 12.5 cps and coupling to the adjacent CH's of 5.5 cps. For ZnSAL-DPT, the peak at  $-4.4$  resembles more a quartet, which could arise from equal coupling to the other  $\alpha$ -CH and  $\beta$ -CH's. This would indicate that there might be some slight difference in structure, or in methylene chain configuration, between the ZnSAL-DPT and ZnSAL-MeDPT complexes (*vide infra*). However, since long-range coupling to the NH is also possible, no definite conclusions can be drawn. The assignment of the ring protons on the basis of multiplet structure and substitution is trivial. The peak locations, relative to TMS, are (in cps at 60 Mcps): 3-H,  $-404$ ; 4-H,  $-430$ ; 5-H,  $-387$ ; 6-H,  $-422$ ; 3-CH<sub>3</sub>,  $-128$ ; 4-CH<sub>3</sub>,  $-130$ ; 5-CH<sub>3</sub>,  $-131$ .

The pmr traces of three nickel chelates are illustrated in Figure 3 over the region where all the ring protons lie. What becomes immediately obvious is that there appears not a single peak per ring position, but two separate resonances. For some samples, as many as 21

peaks were observed with the complex containing a total of 23 protons. That two peaks arise per ring position was verified by the use of substituents, where peaks disappeared in pairs upon chloro substitution and shifted and tripled in intensity upon methyl substitution. The difference in resonance position for a pair of peaks is as large as 263 cps in chloroform solution. Also, the N-CH<sub>3</sub> peak in the MeDPT complexes illustrates that there should be two separate resonances per ring position by the fact that the intensity ratio for this methyl group to any single ring peak is only 3:1, instead of the expected 3:2. In a few cases, the 6-H peak was not split, and this resulted in the only peak attributable to this position having twice the intensity of any of the other "split" proton peaks.

Assignment was performed completely by substitution, as the line widths were too great ( $\geq 10$  cps) to resolve any multiplet structure in all but a few cases. For 3-Cl-NiSAL-MeDPT, the two 4-H peaks each showed a doublet, as did the 6-H, while the 5-H exhibited a triplet, as is expected. This sample thus serves to confirm the 6-H assignment, as complexes with substituents at this position were not prepared. The peak positions are found to be quite independent of ring substituents, except that the 4-H resonated slightly further downfield upon substituting at the 3 position, as has been observed in other related chelates of nickel.<sup>13</sup>

The temperature dependences of the ring proton resonances of NiSAL-DPT and NiSAL-MeDPT in chloroform are plotted as a function of  $1/T$  in Figure 4, and verify that the shifts generally follow a Curie law,<sup>14</sup> eliminating any equilibrium such as was found for a number of nickel(II) systems.<sup>9,11-13,15,16</sup>

Assignment of the ring protons was facilitated by the fact that they exhibited line widths significantly

(18) J. S. Waugh and R. S. Fessenden, *J. Am. Chem. Soc.*, **79**, 846 (1957); D. J. Wilson, D. J. V. Boekelheide, and R. W. Griffin, *ibid.*, **82**, 6302 (1960).

r than for the remaining protons. Because of the solubility for most of the complexes and excessive dilutions, it was possible to locate all of the nonring protons in only a very few samples. Aside from the proton resonances for NiSAL-DPT in chloroform, the following peaks (cps) and their relative intensities have been observed: -13,300 (1), -10,500 (1), 0 (2), -4200 (2), -1960 (1), -850 (1), 80 (1), 529 (1), 780 (1), and -14,980 (1) and -16,700 (1). The four peaks between 80 and 780 cps can be entirely assigned to the four  $\beta$ -CH's, since only for this position do spin polarization effects predict up-contact shifts. Both  $\sigma$  and  $\pi$  spin density result in upfield shifts for  $\alpha$ -CH's and  $\gamma$ -CH's. This assignment is also consistent with the smaller line widths of these peaks, as they are one bond further removed from the nickel than the other two methylene positions. Two peaks at -14,980 and -16,700 cps can be assigned to the azomethine protons, again because of narrower lines due to a greater distance from the nickel.

A large downfield shift for this position has been observed in other nickel chelates with salicylaldimines.<sup>15</sup> The two larger peaks at -6500 and -4700 cps can be assigned to the  $\gamma$ -CH's, since the  $\gamma$ -CH<sub>2</sub> resonates at -4700 cps, and there would not be expected to be very much difference in the peak position of the aminomethyl and aminomethylene groups. The four peaks at -13,300, -10,500, -1960, and -850 cps, which must arise from the  $\alpha$ -CH's, are assigned consistently in that the largest spread of  $\alpha$ -CH's was also observed in the diamagnetic chelates. The presence of unpaired spin in the paramagnetic system just greatly amplifies the effect. The assignments for the  $\alpha$ -CH's and  $\gamma$ -CH's are speculative, however, and cannot be fully justified. It will be shown later that these assignments are consistent with certain aspects of these complexes. This scheme of assignments holds true for all DPT complexes, as only minor differences in position occur. The N-H resonance was found presumably because it is too close to the

the NiSAL-MeDPT series, the nonring protons are found at: -13,200 (1), -11,400 (1), -6700 (4), 0 (3), -1630 (1), -1000 (1), -187 (1), 112 (1), 227 (1), and -11,930 (1) and -13,520 (1), cps. The four peaks between -187 and 227 cps are assigned to the  $\beta$ -CH's, and those at -11,930 and -13,520 cps to the azomethine protons, on the same basis as for NiSAL-DPT. The peak at -4700 cps is assigned to the aminomethyl group, due to its relative intensity and its absence in the DPT chelates. The peak of intensity 4 at -6700 cps is attributed to the  $\gamma$ -CH's, again because of its position being so similar to the aminomethyl. The remaining peaks must belong to four  $\alpha$ -CH's.

As can be seen from a comparison of the assignments for the DPT and MeDPT complexes, the resonance patterns are quite similar. Significant differences are seen in the spread of the  $\beta$ -methylene shifts, the extent of upfield shift for the azomethine protons, and the fact that the  $\gamma$ -methylene protons give rise to two peaks in the DPT chelates, but only a single broad resonance (cps) for the MeDPT complexes.

**Origin of the Double Peaks.** The appearance of twice the number of peaks expected, even after

considering the nonequivalence of the methylene protons resulting from ring formation, can be considered to arise from two likely situations. One would be the presence of two distinct species in solution with differing shift patterns, the other possibility being that we have but one species, but the two salicylaldimine fragments are nonequivalent, such that their shift patterns differ.

The former case could result from two geometrical isomers or from optical isomers. There have been reported<sup>12,15</sup> some cases of similar "doubling" of lines where the origin was traced to the presence of optical isomers. The doubled peaks did not appear with equal intensity, and both sets of peaks were indicative of identical spin distributions, with only a small scaling in magnitude between them.<sup>12,15</sup> Also, the splittings<sup>12,15</sup> represented only a very small fraction of the total shift. In the present study, it is found that the doubled peaks always appear with equal intensity, and this observation holds true over a wide temperature range and in a number of solvents. In view of these observations, plus the fact that the crystal structure<sup>2</sup> showed only one geometrical isomer, the doubling could only arise from optical isomers. However, the two sets of peaks for these five-coordinated complexes display significantly different shift patterns or spin distributions, since the splitting is not at all proportional to the shift magnitude. Often the smallest shift exhibits the largest splitting and *vice versa*. Moreover, the splitting here represents up to 100% of the shift in some cases. Therefore, though these complexes possess no center of symmetry and optical isomers have been observed,<sup>2</sup> their presence in solution cannot explain the observed pattern of peak splittings.

It can be shown, however, that the properties of the observed splittings are consistent with the presence of only one species in solution, with such coordination of the pentadentate ligand that the two salicylaldimine fragments are nonequivalent in some major respect. In NiSAL-MeDPT, for example, the only two positions for which no splittings are observed are the N-CH<sub>2</sub> and the  $\gamma$ -CH's. If two species produced the doubling, it might be expected that these positions should also display a splitting. However, for the case where we have only one species in solution with nonequivalent aromatic fragments, it is obvious that the N-CH<sub>2</sub> "belongs" to both fragments, such that no splitting can be expected. Furthermore, the  $\gamma$ -CH's are next nearest to this equivalence point, such that it would not be unexpected that they show small or negligible splittings. For NiSAL-DPT, the  $\gamma$ -CH's do split, but only into two peaks. Even in this complex, however, this splitting is the smallest for the methylene protons when expressed as fraction of the total shift. It should be pointed out here that a splitting of the  $\gamma$ -methylene peak into two resonances can arise from the effect of ring formation upon coordination to the nickel, even though this splitting was not observed in the diamagnetic zinc complex. The reason for this is that the effect of the unpaired spin can magnify an unobservably small chemical-shift difference in the diamagnetic chelate so that it is readily seen in a paramagnetic complex. However, the splitting of any methylene group into four peaks will only arise through the additional effect of nonequivalence of the two sides of the ligand.

The splitting of a methylene group into four peaks is most convincingly demonstrated in the pmr trace of 5-Cl-NiSAL-DPT, where the elimination of the 5-H peaks clearly reveals two sets of split peaks. The assignment for the  $\beta$ -CH's is quite definite, as no spin-transfer mechanism would result in upfield shifts for the  $\alpha$ -CH's or  $\gamma$ -CH's.

The observed shifts<sup>14</sup> must arise from either a contact interaction or from the dipolar interaction, should the nickel possess an anisotropic  $g$  tensor. In view of the similarity of the presently observed shift patterns to that observed for the tetrahedral chelates,<sup>15</sup> and the fact that methyl substitution always produces shifts of opposite sign to that of the proton,<sup>9,10,19</sup> the shifts must arise primarily from unpaired spin in the ligand highest filled  $\pi$  orbital. However, since the splittings are not proportional to the shift, it is indicated that the spin distribution for the two rings must differ significantly. Isotropic shifts resulting, in part, from  $\sigma$  density<sup>20,21</sup> for one of the rings could be a possibility, as would differing extents of interaction with higher ligand orbitals.<sup>22-24</sup> Both effects have been reported.<sup>20-23</sup> Because of the lack of any symmetry element for these complexes, the spin can probably be delocalized into any ligand orbital.

In order to be able to attribute the splittings to a different extent of dipolar interaction with the two rings, the two aromatic fragments must be oriented differently with respect to the major axes of the chelate; otherwise this interaction will affect both rings identically. For shift differences between the rings as large as 263 cps, the anisotropy will have to be very large, and the difference in ring orientations must represent a large deviation from equivalence. Nothing is known about the  $g$ -tensor anisotropy, due to the lack of esr data. Attempts to observe the esr signal for these complexes failed, perhaps due to large zero-field splittings. The magnetic moments for these complexes are inconsistent with sizable anisotropy, and the inverse cube of the distance dependence<sup>14</sup> of the dipolar interaction makes it unlikely that it could cause such large splittings. However, both the contact and dipolar interaction are thus indicated as possible origins of the double set of peaks, as long as the two salicylaldehyde fragments are nonequivalent.

Such origins for the set of double peaks are quite consistent with the known structure of NiSAL-MeDPT, where the two aromatic fragments are seen to be slightly nonequivalent.<sup>2</sup>

The nonequivalence of the two SAL arises from the fact that the known structure lies somewhere between a trigonal bipyramid and a square pyramid. Steric effects of the methylene chains dictate that the two azomethine nitrogens tend to remain *trans* to each other, as verified in the X-ray analysis,<sup>2</sup> such that a trigonal bipyramidal structure would produce equivalent SAL rings. Coordination with pyridine shows that these ligands readily take up a square-pyramidal con-

formation,<sup>1</sup> as required in octahedral coordination. The two square-pyramidal structures consistent with *trans*-azomethine bonding are labeled I and II, for the SAL rings *cis* and *trans* to each other, respectively.

Of these two conformations, only I would produce non-equivalent SAL rings. It can be easily seen that for this case the two SAL rings would see radically differing ligand fields. Structure II, like the trigonal pyramidal form, would not produce splittings. It could thus be supposed that the extent of ring nonequivalence, as evidenced by the splittings, will increase with structure changes tending to approach I. The great similarity of the crystal and solution spectra indicates no major structure changes upon dissolution;<sup>1</sup> however, small changes in bond angles, perhaps a few degrees, cannot be precluded, as evidenced by the temperature and solvent effect on the splittings (*vide infra*).

The actual structure in any solvent is probably the result of a number of factors, such as repulsion between bonding ligand atoms, steric effects of the methylene chains and the amino nitrogen substituent, and relative crystal field stabilization energies, cfse. The atomic repulsions are likely to be insignificant, inasmuch as related salicylaldehyde ligands readily form octahedral complexes.<sup>12,13</sup> The steric effect is definitely expected to exert a strong influence, probably favoring the trigonal bipyramidal structure, where the bands in the methylene chains are minimized. Crystal field calculations<sup>25</sup> have indicated that the cfse favors the square pyramid, though the high degree of covalent bonding<sup>26</sup> in salicylaldehyde could make such calculations inapplicable in the present case. The effect of coordinating and noncoordinating solvents upon the observed splittings will be seen to shed light on the pentadentate ligand conformation in the octahedral adducts and relate to the importance of steric effects in determining the solution structure.

**Pmr Spectra in Deuteriopyridine.** As shown previously,<sup>1</sup> these five-coordinated complexes all react with 1 mole of pyridine to form the adducts, NiSAL-RDPT·py. The observed isotropic shifts in this solvent are given in Table II. As is readily observable, the shifts for the pure five-coordinated complexes and their octahedral pyridine adducts differ significantly. The shifts are much smaller in the adduct for all but the 4-H position, and the alternation of signs for adjacent positions, very obvious in chloroform solution, almost disappears in pyridine. In addition, only one peak per ring proton is now observed in each case except that of the 4-H peak in 3-CH<sub>3</sub>-NiSAL-DPT, where a splitting of about 16 cps remains. The peaks were generally too broad (25 to 75 cps) to resolve any smaller splittings. Assignment was carried out by substitution. However, the 5-H and 6-H peaks were found so close to each other that it was necessary to verify their

ment by slowly adding pyridine to chloroform solutions of NiSAL-DPT and NiSAL-MeDPT. The ring resonance position as a function of excess pyridine is recorded in Figure 5.

The disappearance of the double peaks upon adduct formation is readily explained by the fact that, upon coordination of pyridine, the octahedral field produces more or less equivalent ligand fields for both SAL rings. That ring nonequivalence has not totally disappeared is indicated by the 16-cps splitting of the 4-H peak in NiSAL-DPT. This splitting is larger than the expected spin-spin coupling. It might thus be concluded that the ring nonequivalence in pyridine is reduced by adduct formation, such that the splittings are very small and are probably obscured by line broadening in all cases except the 3-CH<sub>3</sub>-NiSAL-DPT.

In the pyridine adduct, the chelate must arrange itself in either conformation I or II. Of these two, only conformation I result in nonequivalent salicylaldimine rings and thus splittings should be observed. The 16-cps splitting observed for the one complex adduct with its very narrow line widths indicates that the more likely chelate arrangement is I. This conformation of the chelate in the adduct may be a bit surprising, since the "opening" or clearest approach to the five-membered complex is bisecting the O<sub>1</sub>-Ni-O<sub>2</sub> angle. However, models show that the steric strain in the chelate chains resulting from structure II is quite large and that I is more favorable.

The pattern of the isotropic shifts for the pyridine adduct closely resembles that observed for other octahedrally coordinated nickel(II) complexes with related ligands.<sup>12,13</sup> The shifts display some characteristics arising from spin in the  $\pi$ -ligand orbitals, since a large anisotropy does exist, and protons and methyl groups show shifts of opposite sign for any position.<sup>9,10,19</sup> However, the distribution is inconsistent<sup>15</sup> with that expected for delocalization into the top bonding ligand orbitals and therefore other interaction may well be present. This problem will be treated elsewhere.<sup>24</sup>

**Effect of Noncoordinating Solvents.** Although isotropic shifts for both the NiSAL-MeDPT and NiSAL-DPT chelates exhibit quite similar patterns, a characteristic difference between the two series of complexes is readily observed. In Table I, in addition to the isotropic shifts, we list also for each ring position the difference, or splitting, between the two peaks,  $\delta$ , in cps. From a comparison of the analogous complexes, one with R = H, the other with R = CH<sub>3</sub>, we concluded that the splittings,  $\delta$ , are always larger for the methyl complex than for the latter complex, sometimes by a factor of 2-3. This is true for every position save 6-H, where no splittings appeared for the DPT complexes at room temperature and only very small ones for the MeDPT series. The splittings for any given ring position do not vary significantly upon substitution at the other ring position. The methyl splittings for any position are always smaller than for the proton.

The conclusion which appears most evident is that if the splittings can be interpreted as arising from nonequivalence of the two aromatic parts of the chelate, the extent of this nonequivalence is significantly larger for the NiSAL-DPT than for the NiSAL-MeDPT complexes in chloroform. The splitting for any position should not be taken indiscriminately

as an index of this nonequivalence, since the electronic origin of the splittings in all probability does not affect all ring positions identically. However, if we sum over all the ring positions, we obtain the total splitting parameter,  $\Delta_T$ , which should be a reasonable measure of the extent of nonequivalence. This splitting parameter,  $\Delta_T$ , is also given for each complex in Table I. Comparing this parameter for any two complexes differing only in R, we find  $\Delta_T$  for the NiSAL-DPT consistently larger by a factor 2.2-2.5 than for the NiSAL-MeDPT complex. This ratio of parameters is remarkably constant for all complexes where  $\Delta_T$  can be summed over at least three ring positions.

Within the supposition that the solution structure does not deviate appreciably from that observed in the solid, and that the extent of ring nonequivalence increases as the structure deviates slightly in the direction of structure I, the difference in  $\Delta_T$  between the DPT and MeDPT complexes in chloroform indicates that their structures differ slightly, with the former complexes displaying a structure slightly closer to I than the latter. This difference in proton splittings between the two series was also observed for the methylene protons. As indicated earlier, the  $\beta$ -CH's are spread over  $\approx 420$  cps and  $\approx 700$  cps for the MeDPT and DPT chelates, respectively. Similarly, the  $\gamma$ -CH's produced but a single peak in NiSAL-MeDPT, while NiSAL-DPT showed two peaks. These methylene proton splittings are consistent with the ring  $\Delta_T$  parameters for the two series, and verify their apparent difference in ring nonequivalence, and thus structure. Unfortunately, nothing definite can be stated about the magnitude of the differences in structure between the two series, since it is not known how the splittings depend upon small variations of the bonding angles. However, changes of just a few degrees could be considered quite consistent with the observed changes in view of the high sensitivity of pmr measurements.

The difference in structures for these complexes depending on the R substituent seems to reflect steric effects.<sup>27</sup> As indicated above, these structures are probably determined by a compromise between the steric effect, probably favoring a trigonal bipyramid, and the crystal field, which favors a square pyramid.<sup>26</sup> Since the relatively more bulky methyl group will increase the steric effect in the NiSAL-MeDPT chelates more than the proton in the NiSAL-DPT series,<sup>27</sup> a structure for the former complexes tending more toward I should not be unexpected. That the steric effect of the methyl group influences the structure draws support from the equilibrium constant data for these complexes with pyridine.<sup>1</sup> As shown in Figure 5, for any given excess of pyridine in the two equally concentrated solutions of NiSAL-DPT and NiSAL-MeDPT, the extent of octahedral coordination, as determined by the pmr shift, is always greater for the former chelate. This indicates that the aminomethyl group must provide some steric inhibition<sup>1</sup> toward six coordination for NiSAL-MeDPT. This characteristic difference in equilibrium constants for the two series is observed also for all the ring-substituted isomers.

In order to determine if the solution structure for these complexes is dependent upon solvent, the isotropic shifts were measured in seven other solvents.

(27) F. G. Mann and R. H. Watson, *J. Chem. Soc.*, 2772 (1958).

In Tables III and IV we list the observed shifts, the splitting,  $\delta$ , and the total splitting parameter,  $\Delta_T$ , for 5-CH<sub>3</sub>-NiSAL-MeDPT and 3-CH<sub>3</sub>-NiSAL-DPT, respectively, in each of eight noncoordinating solvents.

Tables III and IV clearly indicate that the splittings are indeed sensitive to the solvent, particularly for 5-CH<sub>3</sub>-NiSAL-MeDPT. Again, the  $\delta$ 's should not be taken individually as indications of the extent of ring nonequivalence, but the sum over the four ring positions,  $\Delta_T$ . It is readily observed that the four ring positions are affected differently by the various solvents in some cases. For the MeDPT chelate,  $\Delta_T$  varies over the range 147–407 cps, while the DPT complex shows much less variation. The isotropic shift patterns are essentially identical in all the solvents. In none of the solvents listed in Tables III and IV does any additional coordination of the five-coordinated species occur. This was verified by studying the pmr lines of the solvent.

The dependence of  $\Delta_T$  on the solvent indicates that the extent of ring nonequivalence, and hence the structure, are also a function of the solvent. Since there exists no direct bonding between these solvents and the five-coordinated chelates, the solvent sensitivity of the splittings and structure must reflect some sort of variable solvation effect. The observed splitting parameter,  $\Delta_T$ , increases for these solvents in the order CCl<sub>4</sub> < CS<sub>2</sub>  $\approx$  C<sub>6</sub>D<sub>6</sub> < CDCl<sub>3</sub> < CD<sub>3</sub>COCD<sub>3</sub> < CD<sub>3</sub>OD < CD<sub>3</sub>NO<sub>2</sub> < CD<sub>3</sub>CN, for the 5-CH<sub>3</sub>-NiSAL-MeDPT complex. This apparent increase in ring nonequivalence, as indicated by  $\Delta_T$ , correlates very well with the dielectric constants for these solvents, also included in Table III under  $\epsilon$ . Since the ring nonequivalence increases as I is approached, the correlation between the parameter  $\Delta_T$  and dielectric strength implies that increasing solvating power tends to stabilize the square-pyramidal structure (I) over the more trigonal bipyramidal one in solution for the MeDPT complex, or that the square-pyramidal structure is more highly solvated than the trigonal bipyramid. A very similar solvation effect has been observed<sup>16</sup> for the nickel(II) chelates of aminotroponimine, where the sensitive solvent dependence of the square-planar, diamagnetic  $\rightleftharpoons$  tetrahedral, paramagnetic forms was explained by the higher solvation of the square-planar form. Such solvation may be considered analogous to the microcrystalline ordering postulated<sup>28,29</sup> to explain the line-width differences for the hyperfine components in the esr spectra of square-planar complexes. The extent of stabilization of the square pyramid over the trigonal bipyramid forms by this mechanism could be expected to increase with the solvent dielectric strength, though solvent shape and size probably also play an important part.

Another possible mechanism which would stabilize I and would be expected to produce the observed dependence on the dielectric strength is that of solvation of the complex as a whole, without any ordering of solvent molecules, which decreases the repulsion between the oxygens, thereby allowing them to take up a more *cis* position. Either mechanism would account for the increased stabilization of the square-pyramidal structure with solvent dielectric strength, but *only* if the con-

formation of the square-based structure approaches I. The observed changes in  $\Delta_T$  with solvents are quite inconsistent with structure II as a limit.

For the 3-CH<sub>3</sub>-NiSAL-DPT complex, the variation in  $\Delta_T$  with solvent is much smaller than that for the DPT complex and does not seem to indicate any significant dependence on dielectric constant, except that the splittings are again largest in nitromethane and acetonitrile. The variations in  $\Delta_T$  with solvent represent only a 10–20% deviation from the average, implying that the extent of nonequivalence of the two aromatic rings, and hence the solution structure, is more or less independent, or at least does not demonstrate the striking dependence noted for 5-CH<sub>3</sub>-NiSAL-MeDPT.

Though the pmr spectra of the two other methyl-substituted chelates are available for only a very few solvents due to insolubility, as indicated at the bottom of Tables III and IV, it is observed that the available data are consistent with the above conclusions.

From Table I, we note for the DPT series, where it appears that the ring substituent does not significantly influence the splittings and thus the structure, that the 5-CH<sub>3</sub> derivative produces a  $\Delta_T \approx 1.3$  times that for the 3-CH<sub>3</sub> isomer. This ratio of  $\approx 1.3$  for the two methyl-substituted isomers holds also for the MeDPT series. It can therefore be concluded that if the structures of 5-CH<sub>3</sub>-NiSAL-MeDPT and 3-CH<sub>3</sub>-NiSAL-DPT were identical in any given solvent, then their ratio of  $\Delta_T$ 's should also be  $\approx 1.3$ . From a comparison of  $\Delta_T$ 's for the same solvent in Tables III and IV, it is observed that this ratio is about 0.5 for the solvents of low dielectric strength and increases to 1.0 for solvents with high dielectric constant. This implies that the structures of the DPT and MeDPT complexes, or their extents of ring nonequivalence, differ, with the former chelate possessing a more nonequivalent pair of SAL fragments, but with the *difference* between the two series of complexes decreasing as the solvent dielectric strength increases. As a strong solvent effect was observed only for the MeDPT chelates, and since the difference in solution structure for the DPT and MeDPT complexes was attributed to the steric effect of the aminomethyl group, it appears that solvation tends to diminish the importance of this steric effect.

This difference between the two series of complexes is also evidenced in the temperature dependence of the ring proton shifts and serves to support the supposition that steric effects account for the difference in structure, as indexed by the splitting term,  $\Delta_T$ . As illustrated in Figure 4, the isotropic shifts for NiSAL-DPT follow the Curie law exactly, and hence so do the splittings,  $\delta$ , as expected. For the NiSAL-MeDPT chelate, however, though the shifts generally follow the Curie law, it is noticed, particularly for 3-H and 5-H, that the two peaks for each position diverge much more than predicted by a Curie behavior. This is demonstrated in the temperature dependence of the splittings,  $\delta$ . It clearly shows that  $\delta$  for 3-H decreases with temperature much more slowly than predicted while  $\delta$  for 5-H actually *increases* with temperature, opposite to expectations. This effect can be interpreted such that if the smaller splittings for the MeDPT series arise because steric effects tend to stabilize a more trigonal-bipyramidal-like structure, where the extent of ring nonequivalence is less than in the DPT series, then in-

#### ry

observed "doubling" of the pmr peaks in the rdinated complexes is attributed to the presence ingle species in solution which possesses non- lent salicylaldimine fragments. The magnetic ivalence arises from the fact that the two aromatic nts see slightly different ligand fields, as indi- n the known X-ray structure. The pmr spectra line are consistent with octahedral coordination, e splitting of peaks disappears or is greatly re-

The appearance of a 16-cps splitting in one idicates that the conformation of the penta-

dentate ligand in the pyridine adduct has the salicyl- aldimine fragments bonded *cis* to each other.

Changes in the observed splittings are related to slight changes in solution structure. Small deviations from the crystal structure in the direction of a square pyramid with the aromatic rings *cis* to each other increase the extent of nonequivalence of the aromatic rings, giving rise to larger splittings. The sum of the splittings for the four ring positions indicates that the extent of ring nonequivalence is greater for the DPT than the MeDPT complexes and is attributed to the steric effect of the aminomethyl group which tends to favor a more trigonal-bipyramidal structure. The splittings for the methylene protons are consistent with these conclusions, as are the equilibrium constant data for the pyridine adduct formation and the temperature dependence of the ring splittings for the two series of complexes.

The magnitude of the splitting parameter and hence solution structure are shown to be very solvent sensitive for the MeDPT chelates and correlate well with solvent dielectric strength. The increase of splittings with solvent strength indicates that the structure tends to approach a square-pyramidal structure with the SAL *cis* to each other. The solvent effect is interpreted as arising from preferred solvation of the square-pyramidal over the trigonal-bipyramidal structure, apparently working to counter the steric effect of the aminomethyl group. The temperature dependence of the splittings confirms this assumption. For the DPT chelates, the splittings and solution structure are insignificantly affected by either solvent or temperature. The ability to observe these changes, in spite of the fact that absorption spectra are essentially independent of substituents or solvent, is related to the much greater sensitivity of the pmr method.

# The Off-Diagonal Matrix Element in Molecular Orbital Calculations for Metal Complexes

Douglas D. Radtke<sup>1</sup> and Richard F. Fenske

Contribution from the Department of Chemistry, University of Wisconsin, Madison, Wisconsin 53706. Received October 14, 1966

**Abstract:** This work concerns an investigation of those considerations involved in the evaluation of the off-diagonal matrix elements which arise in molecular orbital calculations for metal complexes. The use of  $FG_{ij}(H_{ii} + H_{jj})/2$  and related attempts to correlate  $H_{ij}$  with the group overlap integrals,  $G_{ij}$ , by a multiplicative factor,  $F$ , is examined from theoretical considerations and calculational results. It is shown that terms of considerable magnitude, which do not vary as functions of the overlap integrals, make substantial contributions to the off-diagonal elements. Hence, unpredictable fluctuations in the  $F$  factor occur, and the need for wide variations in the choices of  $F$  factors in previous calculations is understood. Evidence is also presented which indicates that sums of two-center electrostatic interaction integrals vary from complex to complex in a fashion analogous to the corresponding nuclear attraction integrals. Consequently, indications are that the former integrals may be evaluated from the latter in a systematic way.

Since the introduction of the Wolfsberg-Helmholz calculations<sup>2</sup> for the evaluation of the electronic energy levels in transition metal complexes, the matrix elements in the secular determinant,  $|H_{ij} - EG_{ij}|$ , have been approximated by a variety of techniques. In a previous paper<sup>3</sup>, we emphasized the importance of including the two-center Coulomb and exchange integrals as well as the free-ion orbital energies for the evaluation of the metal and ligand diagonal terms. Other authors<sup>4-6</sup> have introduced similar adjustments to the diagonal terms using various means for approximating the integrals involved. However, most of these authors have continued to use an approximation for the off-diagonal matrix element which involves the overlap integral,  $S_{ij}$ , or the group overlap integral,  $G_{ij}$ . It is the purpose of this paper to examine the relation between the overlap integral and the off-diagonal matrix element.

It is interesting to note the various attempts to systematize the relationship between  $S_{ij}$  and the off-diagonal term. The original Wolfsberg-Helmholz calculation<sup>2</sup> set  $H_{ij} = FG_{ij}(H_{ii} + H_{jj})/2$  with  $F_e = 1.67$  and  $F_r = 2.00$ . Yamatera<sup>7</sup> used the same expression for his calculations on  $\text{Co}(\text{NH}_3)_6^{+3}$ . The self-consistent charge and configuration (SCCC) method as originally applied by Ballhausen and Gray<sup>8</sup> to the vanadyl ion employed  $H_{ij} = FG_{ij}\sqrt{H_{ii}H_{jj}}$  with  $F_e = F_r = 2.00$ . Among others, this relation has been employed by Lohr and Lipscomb<sup>9</sup>, Fischer,<sup>10</sup> Johansen and Ballhausen,<sup>11</sup> and in several applications by Gray and co-workers.<sup>12-14</sup>

However, Cotton and Haas<sup>15</sup> have pointed out that in a series of ammine complexes,  $F_r$  had to be varied from 1.82 to 2.30 in order to obtain agreement with experimental values of  $\Delta = 10Dq$ . Similarly, the more recent applications of the SCCC method to halide and oxide complexes<sup>16</sup> used  $F_r = 2.10$  with  $F_e$  slowly varying from 1.53 to 1.81. In all of these calculations, the diagonal term consisted only of the free ion orbital energy and/or the ionization potential of the corresponding hydride.

Other variations for  $H_{ij}$  have been presented. Cusachs<sup>17</sup> suggested  $H_{ij} = (2 - |S_{ij}|)(H_{ii} + H_{jj})G_{ij}/2$ , while Yeranov<sup>18</sup> offered  $H_{ij} = FG_{ij}[2(H_{ii}H_{jj})/(H_{ii} + H_{jj})]$ , and Kettle<sup>19</sup> employed the simplest relation,  $H_{ij} = KS_{ij}$  with  $k$  as a variable.

A further complication arises with the introduction of the two-center Coulomb integrals in the evaluation of  $H_{ii}$  and  $H_{jj}$ .  $H_{ii} = \epsilon_{ii} + \text{Coulomb repulsion terms}$ .  $\epsilon_{ii}$  is the orbital energy of the electron in the free ion which is frequently approximated by the negative of the valence-state ionization energy of the appropriate free ion. The two-center Coulomb repulsion integrals are positive. The effect of the latter terms is to raise the values of  $H_{ii}$  and  $H_{jj}$  appreciably above their original negative values, that is, to make them smaller in absolute value.

Indeed, it is possible and actually occurs<sup>20</sup> that in complexes of high negative charge,  $\text{FeF}_6^{-3}$  or  $\text{CrCl}_6^{-3}$ , for example, at self-consistent charge the Coulomb repulsion terms are larger in magnitude than the orbital energies for the metal 3d, 4s, and 4p orbitals so that  $H_{ii}$  for the metal is positive. Such a situation is possible because the calculations do not include the positive ions of the species, for example, the  $\text{K}^+$  ions in  $\text{K}_3\text{TiF}_6$ , which are presumed to add simply a constant potential

system. At the same time, the ligand diagonal  $H_{jj}$ , is negative so that use of the root-mean-method results in imaginary values. To circumvent this dilemma, Ros<sup>21</sup> returned to the original Herg-Helmholz average. But even this method led to difficulty in terms of the coefficients in the ligand orbitals. Consider solving the secular equation for the eigenvalues

$$[H(3d,3d) - E] + b[H(3d,3p) - EG(3d,3p)] = 0 \quad (1)$$

An expression can arise in the solution of a  $2 \times 2$  matrix involving  $\text{FeCl}_6^{-3}$ , for example. The term  $a$  is the coefficient of the metal 3d wave function in the ligand orbital, while  $b$  is the coefficient for the symmetry-adapted ligand orbitals.  $H(3d,3d)$  is the metal orbital matrix element,  $H(3d,3p)$  is the off-diagonal element between the 3d and 3p orbitals, and  $G(3d,3p)$  is the positive overlap integral. Consider the case where  $H(3d,3d)$  is positive and  $H(3p,3p)$  is slightly negative in value.<sup>22</sup> The energy of the bonding orbital,  $E_1$ , will be more negative than either  $H(3d,3d)$  or  $H(3p,3p)$ , so that  $[H(3d,3d) - E]$  as well as  $-EG(3d,3p)$  are positive.

For a positive value of  $a$

$$b = -\frac{a[H(3d,3d) - E]}{H(3d,3p) - EG(3d,3p)} \quad (2)$$

to have a positive value in keeping with the bonding character of the orbital, not only must  $H(3d,3p)$  be positive but it must be larger in absolute value than  $EG(3d,3p)$ . But if one uses

$$H(3d,3p) = FG[H(3d,3d) + H(3p,3p)]/2$$

the Coulomb terms included for the diagonal elements it can and does occur that  $|H(3d,3d)| > |H(3p,3p)|$  so that  $H(3d,3p)$  is positive and one is led to the erroneous conclusion that the bonding orbital is bonding in character. In any event, the off-diagonal term is substantially decreased in magnitude if evaluated from the  $H_{ii}$  terms in this way. This situation cannot be rectified simply by the addition of the diagonal terms of some arbitrary negative value that will allow both terms to become negative. In principle, the addition of such a term,  $-Z$ , to the diagonal should not alter the calculated energy  $E$ , relative to each other or to the starting levels,  $H_{jj}$ . Without loss of generality, this can be achieved by recourse to a simplified  $2 \times 2$  secular determinant in which  $H_{ii} = H_{jj}$ . Then

$$(H_{ii} - E)^2 - (H_{ij} - EG_{ij})^2 = 0 \quad (3)$$

$$E_1 = (H_{ii} - H_{ij})/(1 - G_{ij}) \quad (4)$$

$$E_1 - H_{ii} = [(H_{ii} - H_{ij})/(1 - G_{ij})] - H_{ii} \quad (5)$$

A constant potential for the diagonal terms yields  $\langle \psi_i | = -Z$  so  $H_{ii}'$  becomes

$$H_{ii}' = H_{ii} - Z \quad (6)$$

In the off-diagonal term, one obtains  $-Z\langle \psi_i | \psi_j \rangle = -ZG_{ij}$  so  $H_{ij}'$  becomes

$$H_{ij}' = H_{ij} - ZG_{ij} \quad (7)$$

Ros and G. C. A. Schriert, *Theoret. Chim. Acta*, **4**, 1 (1966). This situation is not fictional but has occurred frequently in our work dealing with complexes with  $-3$  charges.

Substitution of these terms into

$$(H_{ii}' - E')^2 - (H_{ij}' - E'G_{ij})^2 = 0 \quad (8)$$

yields

$$E_1' = [(H_{ii} - H_{ij})/(1 - G_{ij})] - Z \quad (9)$$

Then,  $E_1' - H_{ii}' = E_1 - H_{ii}$ , and constancy of the levels relative to one another is maintained. But this relation holds only if  $H_{ij}' = H_{ij} - ZG_{ij}$ . If one applies the Wolfsberg-Helmholz approximation for the off-diagonal term, then for  $H_{ii} = H_{jj}$

$$H_{ij} = FG_{ij}H_{ii}$$

However, for  $H_{ij}'$ , one obtains

$$H_{ij}' = FG_{ij}(H_{ii} - Z) = H_{ij} - FG_{ij}Z \quad (10)$$

The requirement of unchanging relationships between the levels is maintained only if  $F = 1.00$ . Since this is never the case, introduction of a constant potential to the diagonal terms would be equivalent to the addition of another variable to the calculations, subtly altering the value of the off-diagonal term depending on the size of the chosen potential.

As an alternative to the foregoing undesirable state of affairs, Oleari, *et al.*,<sup>4</sup> have chosen to set  $H_{ij} = FG_{ij}(\epsilon_{ii} + \epsilon_{jj})/2$  where the  $\epsilon$ 's are the orbital energies and  $F = 1.00$  for all interactions with ligand p orbitals and  $F = 0.30$  for metal-ligand interactions involving the ligand s orbitals. This removes the dilemma as to sign for the off-diagonal terms. However, as will be shown, it is our belief that the absolute magnitudes of the terms are too small.

## Theoretical Considerations

Throughout the course of all the various attempts to approximate the off-diagonal terms, the considerations advanced by Richardson,<sup>23</sup> in an A.E.C. publication which unfortunately achieved only limited distribution, have been overlooked. Richardson shows that by application of the Mulliken<sup>24</sup> multicenter integral approximation to both Coulomb and exchange parts of the Fock operator in Roothaan's method for closed shells, the one-electron operator becomes

$$H = -1/2\Delta + V_M + \sum_j V_j$$

where  $-1/2\Delta$  is the kinetic energy operator,  $V_M$  is the potential energy due to the nucleus and electrons of the metal, and  $V_j$  corresponds to the nucleus and electrons of the  $j$ th ligand. Additional information concerning the operator forms of the potentials can be found in our recent publication.<sup>3</sup>

Consider the matrix element  $\langle \phi_i | \mathcal{H} | \chi_i \rangle$ , where  $\chi_i$  is a metal wave function and  $\phi_i$  is a symmetry-adapted linear combination of ligand wave functions,  $\rho_{ij}$ , over the  $j$  ligands. Then  $\langle \phi_i | \mathcal{H} | \chi_i \rangle = C(\rho_i | \mathcal{H} | \chi_i)$  where the constant,  $C$ , is the same coefficient which relates the diatomic overlap,  $S(\rho_{ii}, \chi_i)$  to the group overlap  $G(\phi_i, \chi_i)$ . Then the matrix element can be written as

(23) J. W. Richardson and R. E. Rundle, "A Theoretical Study of the Electronic Structure of Transition Metal Complexes," Ames Laboratory, Iowa State College, ISC-830, U. S. Atomic Energy Commission, Technical Information Service Extension, Oak Ridge, Tenn., 1956.

(24) R. S. Mulliken, *J. Chim. Phys.*, **46**, 497, 675 (1949).

$$(\phi_i|\mathcal{H}|\chi_i) = C\{(\rho_{ii}|-1/2\Delta + V_M|\chi_i) + (\rho_{ii}|\sum_{j=2} V_j|\chi_i) + (\rho_{ii}|V_1|\chi_i)\} \quad (11)$$

For computational reasons, the foregoing expression is a convenient form for the matrix element. However, since the Hamiltonian is Hermetian, it is also possible to write the off-diagonal term as

$$(\chi_i|\mathcal{H}|\phi_i) = C\{(\chi_i|-1/2\Delta + V_1|\rho_{ii}) + (\chi_i|\sum_{j=2} V_j|\rho_{ii}) + (\chi_i|V_M|\rho_{ii})\} \quad (12)$$

If one makes the reasonable approximation that  $\chi_i$  is an eigenfunction of  $-1/2\Delta + V_M$  and correspondingly  $\rho_{ii}$  is an eigenfunction of  $-1/2\Delta + V_1$ , then the first term in  $(\phi_i|\mathcal{H}|\chi_i)$  and  $(\chi_i|\mathcal{H}|\phi_i)$  becomes  $\epsilon_{\chi_i}S(\rho_{ii},\chi_i)$  and  $\epsilon_{\rho_{ii}}S(\rho_{ii},\chi_i)$  respectively. By considering the off-diagonal term as  $H(\phi_i,\chi_i) = 1/2[(\phi_i|\mathcal{H}|\chi_i) + (\chi_i|\mathcal{H}|\phi_i)]$ , one can write

$$H(\phi_i,\chi_i) = C\left\{\frac{(\epsilon_{\chi_i} + \epsilon_{\rho_{ii}})S(\rho_{ii},\chi_i)}{2} + (\rho_{ii}|\sum_{j=2} V_j|\chi_i) + 1/2[(\rho_{ii}|V_M|\chi_i) + (\rho_{ii}|V_1|\chi_i)]\right\} \quad (13)$$

Note that when the first term in the brackets is multiplied by  $C$  it becomes  $(\epsilon_{\chi_i} + \epsilon_{\rho_{ii}})G(\phi_i,\chi_i)/2$  which is identical with the Wolfsberg-Helmholz relationship for  $F = 1.00$ . This latter value, it will be recalled, was employed by Oleari, *et al.*<sup>4</sup> Thus, their approximation assumes the additional Coulomb terms cancel one another. Correspondingly, as Richardson pointed out long ago,<sup>23</sup> the use of  $F$  factors larger than 1.00 in the off-diagonal term attempts to correct by *multiplicative* factors for the *added* potential terms. What Richardson was not in a position to do at the time was to explore the reasonableness of an approximation involving the overlap integral,  $S(\rho_{ii},\chi_i)$ , for evaluation of the two- and three-center electrostatic interactions. As a by-product of our recently completed calculations on chloride complexes in octahedral and tetrahedral symmetry,<sup>25</sup> we have reached the conclusion that estimations of the electrostatic interaction and nuclear attraction integrals involved in  $H(\phi_i,\chi_i)$  cannot be systematically made from the corresponding overlap integral. Consequently, it is not surprising that off-diagonal terms which are estimated from a product function involving overlap integrals should require substantial adjustments, by variable  $F$  factors and the other cited methods, when going from one compound to the next. Furthermore, it does not seem likely that product functions involving the overlap integral only can be systematized to reliably reproduce the value of the off-diagonal matrix elements. Computational evidence of these conclusions is given in the next section.

## Calculations

Examination of eq 13 suggests that the Wolfsberg-Helmholz approximation for the off-diagonal matrix element would be adequate from one complex to another if one of two situations applied: (1) the additional terms,  $(\rho_{ii}|\sum V_j|\chi_i)$ , etc., nearly cancel one another so that the dominant term in the expression for  $H(\phi_i,\chi_i)$  is  $CS(\rho_{ii},\chi_i)(\epsilon_{\chi_i} + \epsilon_{\rho_{ii}})/2$ ; (2) the additional terms dis-

play the same variations from orbital to orbital and compound to compound as do the corresponding overlap integrals. Unfortunately, neither situation appears to hold.

**The Magnitude of the Additional Terms.** Consider the evaluation of the terms for  $H(\phi_i,\chi_i)$  as given in eq 13. As we have previously indicated,<sup>3</sup> the values of  $\epsilon_{\chi_i}$ ,  $\epsilon_{\rho_{ii}}$ , and  $S(\rho_{ii},\chi_i)$  present no computational problems once appropriate consideration is given to the charges and configurations of the metal and ligand species. Furthermore, it is quite reasonable to approximate the three-center interactions by

$$(\rho_{ii}|\sum_{j=2} V_j|\chi_i) = -\sum_{j=2} q_j(1/r_j|\rho_{ii}\chi_i) \quad (14)$$

where  $q_j$  is the calculated charge on the ligand  $j$  as obtained from a Mulliken electron population analysis<sup>24</sup> and  $(1/r_j|\rho_{ii}\chi_i)$  is a three-center nuclear attraction integral. The two remaining terms,  $(\rho_{ii}|V_M|\chi_i)$  and  $(\rho_{ii}|V_1|\chi_i)$ , require special consideration. In terms of our previous techniques,<sup>3</sup> the explicit forms of these terms are

$$(\rho_{ii}|V_1|\chi_i) = \sum_k \bar{b}_{ki}\{2(\rho_{ki}\rho_{ki}|\rho_{ii}\chi_i) - (\rho_{ki}\rho_{ii}|\rho_{ki}\chi_i)\} - Z_1(1/r_1|\rho_{ii}\chi_i) \quad (15)$$

$$(\rho_{ii}|V_M|\chi_i) = \sum_k \bar{a}_{kM}\{2(\chi_k\chi_k|\rho_{ii}\chi_i) - (\chi_k\rho_{ii}|\chi_k\chi_i)\} - Z_M(1/r_M|\rho_{ii}\chi_i) \quad (16)$$

where

$$(\psi_a\psi_b|\psi_c\psi_d) = \int \psi_a^*(1)\psi_b(1)1/r_{12}\psi_c^*(2)\psi_d(2) d\tau$$

$$(1/r_M|\psi_a\psi_b) = \int \psi_a^*(1)1/r_M\psi_b(1) d\tau$$

$\bar{a}_{kM}$  and  $\bar{b}_{ki}$  are the fractions of the electron in the  $k$ th occupied orbital on the metal and ligand 1, respectively, as determined from the electron population analysis. For simplicity it is assumed that all inner-shell electrons, for example, those below the 3d in the metal and below the 3s on a chlorine ligand, can be incorporated into  $Z_M$  and  $Z_1$  which then represent the core potentials rather than the nuclear charges. Even with this simplification the number of different two-center electrostatic interaction integrals associated with eq 16 becomes quite large when  $\chi_k$  includes the 3d, 4s, 4p, and 4d metal wave functions with two or more Slater functions for each of the radial terms. The routine evaluation of all these integrals is computationally time consuming and expensive, particularly when one considers the many off-diagonal terms involved in  $|\rho_{ii}\chi_i\rangle$ . It is for this reason that for routine calculations we have chosen to evaluate  $H(\phi_i,\chi_i)$  by eq 11, since the evaluation of  $(\rho_{ki}\rho_{ki}|\rho_{ii}\chi_i)$  in  $(\rho_{ii}|V_1|\chi_i)$  need be summed only over  $k = ns$  and  $np$ .

In the course of some recently completed computations,<sup>25</sup> we had an opportunity to investigate the off-diagonal term represented by eq 13 within the framework of our computational technique. If one makes the assumption<sup>23</sup> that the 3d orbitals are the only outer metal orbitals sufficiently contracted to result in a meaningful transfer of electron density to the metal and hence one can limit the electron population analysis to these orbitals, then  $(\rho_{ii}|V_M|\chi_i)$  becomes more computationally tractable. We have examined this and the other terms

(25) R. F. Fenske and D. D. Radtke, submitted for publication.

(26) R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833 (1955).

of the off-diagonal element for  $H(3d\sigma, 3p\sigma_1)$  and  $H(3d\pi, 3p\pi_1)$  in  $\text{FeCl}_6^{-3}$  at a self-consistent charge on the metal of +1.75. Within the framework of the Slater average of configuration approximations the calculated values for the various terms are summarized in Table I.

Table I. Terms in  $(3p\sigma_1|\mathcal{H}|3d\sigma)$  and  $(3p\pi_1|\mathcal{H}|3d\pi)$  of  $\text{FeCl}_6^{-3}$

	$(3p\sigma_1, 3d\sigma)$	$(3p\pi_1, 3d\pi)$
$S(\rho_{ii}, \chi_i)$	0.074	0.044
3d orbital energy, ev	-28.49	-28.49
3p orbital energy, ev	-6.86	-6.86
$(\rho_{ii} \sum_{j=2}^5 V_j \chi_i)$ , ev	+1.40	+0.89
$(\rho_{ii} \mathcal{V}_{ii} \chi_i)$ , ev	-3.07	-1.42
$(\rho_{ii} \mathcal{V}_1 \chi_i)$ , ev	-1.30	-0.42
$H(\rho_{ii}, \chi_i)$ , eq 13, ev	-2.09	-0.81
$H(\rho_{ii}, \chi_i)$ , eq 11, ev	-2.01	-0.77
$S(\epsilon_{sd} + \epsilon_{sp})/2$	-1.31	-0.78
$F$	1.60 (1.54) <sup>a</sup>	1.04 (0.99) <sup>a</sup>

<sup>a</sup> The  $F$  value in parentheses is that required to obtain agreement between  $FS(\epsilon_{sd} + \epsilon_{sp})/2$  and  $H(\rho_{ii}, \chi_i)$  obtained from eq 11. The  $F$  value not in parentheses is needed to duplicate  $H(\rho_{ii}, \chi_i)$  by eq 13.

First of all, one notes that there is very good agreement between the values of  $H(\rho_{ii}, \chi_i)$  determined by eq 11 and 13. When one considers the necessary approximations in each of these computations, such agreement is very satisfying. At the very least it indicates a substantial degree of internal consistency within the model framework. It might also be noted in passing that the addition of a constant potential to the Hamiltonian operator for the diagonal terms offers no dilemma for the off-diagonal elements as given by eq 11 or 13 since they would increase by the value  $-ZG(\phi_{ii}, \chi_i)$  as required to maintain the previously mentioned constancy of separation between the eigenvalues.

It is also apparent that the formula,  $FS(\rho_{ii}, \chi_i) \cdot (\epsilon_{xi} + \epsilon_{pi})/2$  with  $F = 1$ , does occasionally yield a value for the off-diagonal term which is approximately correct, as in the case of  $(3p\pi_1|\mathcal{H}|3d\pi)$  for  $\text{FeCl}_6^{-3}$ . However, the relationship is not generally applicable as indicated by the values for  $(3p\sigma_1|\mathcal{H}|3d\sigma)$ . In general, the additional terms in eq 13 do not cancel one another, and they have an important influence on the value of the off-diagonal term.

If one assumes that the good agreement between results from eq 11 and 13 is maintained for other off-diagonal matrix elements, and that the values obtained by these equations are good estimates of the matrix elements, it is a simple task to examine the trends in  $F$  values necessary to obtain agreement between  $FS \cdot (\epsilon_{xi} + \epsilon_{pi})/2$  and the values from eq 11. The  $F$  values for the two complexes,  $\text{FeCl}_6^{-3}$  and  $\text{FeCl}_4^{-}$ , are summarized in Table II. The wide variations in the values for  $F$  within and/or between the two complexes strikingly illustrates the futility of attempting to achieve identity between the sets of off-diagonal terms by means of one or two fixed values of  $F$ . It is obvious that the variations in the off-diagonal terms cannot be systematically related to the changes in overlap only.

**Variations of the Terms from Complex to Complex.** There is additional evidence that one cannot expect a simple correlation of overlap with the corresponding off-diagonal element. This is exemplified by examination of the trends in the term  $(\rho_{ii}|\mathcal{V}_1|\chi_i)$ , whose ex-

Table II.  $F$  Values for  $FS(\epsilon_{xi} + \epsilon_{pi})/2 = (\rho_{ii}|\mathcal{H}|\chi_i)$

<sup>a</sup> Internuclear distance between the metal and chlorine atoms.

PLICIT form is given in eq 15. For simplicity of discussion, it is convenient to examine eq 15 in the ionic limit, that is,  $b_{ki} = 1$  for  $k = 3s$  and  $3p$ . In this case, the two-center electrostatic interaction integrals then become

$$\sum_{k=3s, 3p} 2(\rho_{ki}\rho_{ki}|\rho_{ii}\chi_i) - (\rho_{ki}\rho_{ii}|\rho_{ki}\chi_i)$$

In our previous paper<sup>3</sup> we suggested that this summation might be approximated by the relationship,  $7R \cdot (1/r_1|\rho_{ii}\chi_i)$ , where  $(1/r_1|\rho_{ii}\chi_i)$  is the two-center nuclear attraction integral, the value of 7 accounts for the summation over the s and p orbitals, and  $R$  is a constant which depends upon  $\rho_{ii}$  and  $\chi_i$ . We have now obtained some substantiation that the assumption implicit in our previous work has validity, namely, that the value of  $R$  for a given off-diagonal term is essentially invariant to changes in metal wave function, ligand wave function, and internuclear distance. To test this relationship, we carried out computations of the two-center interactions<sup>27</sup> for three chloride and two fluoride complexes involving octahedral and tetrahedral symmetry with internuclear distances ranging from 1.93 to 2.38 Å. The values of  $R$  for the metal 3d interactions with the ligand ns and np orbitals were then computed from the equation

$$7R(1/r_1|\rho_{ii}\chi_i) = \sum_{k=s, p} 2(\rho_{ki}\rho_{ki}|\rho_{ii}\chi_i) - (\rho_{ki}\rho_{ii}|\rho_{ki}\chi_i) \quad (17)$$

The  $R$  values corresponding to a given  $\rho_{ii}$  and  $\chi_i$  are given in the first part of Table III. Two conclusions

Table III.  $R$  and  $f$  Values as a Function of the Complex

	$\text{TiCl}_4$ (2.18 Å)	$\text{CrCl}_6^{-3}$ (2.34 Å)	$\text{FeCl}_6^{-3}$ (2.38 Å)	$\text{CrF}_6^{-3}$ (1.93 Å)	$\text{NiF}_6^{-3}$ (2.01 Å)
$R(3d\sigma, ns)$	0.78	0.76	0.77	0.76	0.79
$R(3d\sigma, np\sigma)$	0.84	0.83	0.84	0.83	0.86
$R(3d\pi, np\pi)$	0.88	0.88	0.90	0.88	0.90
$f(3d\sigma, ns)$	0.43	0.39	0.38	0.61	0.56
$f(3d\sigma, np\sigma)$	0.46	0.44	0.42	0.60	0.55
$f(3d\pi, np\pi)$	0.36	0.34	0.33	0.45	0.42

can be drawn: (1) each set  $(\rho_{ii}, \chi_i)$  has its appropriate value of  $R$ ; (2) the variations of  $R$  values with changing ligands, metals, symmetries, and distances are within

(27) The two-center electrostatic interaction program adapted to the Control Data Corp. computers was kindly supplied to us by Professor F. A. Matson, Molecular Physics Group, University of Texas, Austin, Tex.

4% of one another. This latter conclusion suggests that changes in electrostatic interactions of the type given by the right-hand side of eq 17 result in a similar change in the corresponding nuclear attraction integral. Having once determined the appropriate  $R$  values by exact calculation of the electrostatic interactions for one complex, one may use the same  $R$  values for related species with reasonable confidence. That this same relation does not hold true for the overlap integrals is indicated by the values of  $f$  in Table III calculated from the relationship

$$7fS(\rho_{i1}, \chi_i) = \sum_{k=3s,3p} 2(\rho_{k1}\rho_{k1}|\rho_{i1}\chi_i) - (\rho_{k1}\rho_{i1}|\rho_{k1}\chi_i)$$

As indicated by the  $f$  values, the range of values within the chlorides is of the order of 10% and changing from chloride to fluoride complexes alters the  $f$ 's by about 30%. Thus, it is apparent that a single  $f$  factor times the overlap integral is incapable of properly approximating this important term in the off-diagonal matrix element.

By a similar study, it is possible to show that there is no consistent relation between the overlap integral,  $S(\rho_{i1}, \chi_i)$ , and the three-center term,  $(\rho_{i1}|\sum_{j=2} V_j|\chi_i)$ , in the off-diagonal element.

## Summary

It seems fairly clear that the use of  $F$  factors which multiply the overlap integrals is incapable of consistent approximation of the off-diagonal matrix elements. On the contrary, there is good indication that the additional terms given by eq 11 or 13 are related to the corresponding nuclear attraction integrals. Since it has been shown that the relative positions and separations of the final energy levels are sensitive functions of the off-diagonal terms, it is not inconceivable that energy levels in systems of low symmetry, such as tetragonal or square-planar symmetry, might be incorrectly ordered in calculations in which the off-diagonal terms have been related to overlap integrals.

On the other hand, it appears that the relation given by eq 17 offers a convenient method to circumvent the time-consuming and expensive calculation of the two-center electrostatic interaction integrals.

## Lithiations of $\alpha$ - and $\beta$ -Dimethylaminomethylnaphthalenes with *n*-Butyllithium and Condensations with Benzophenone. Some Related Results<sup>1</sup>

Robert L. Gay and Charles R. Hauser

Contribution from the Department of Chemistry, Duke University, Durham, North Carolina 27706. Received November 18, 1966

**Abstract:**  $\alpha$ -Dimethylaminomethylnaphthalene was lithiated with *n*-butyllithium in ether-hexane to form a mixture of the 8- and 2-lithioamines in which the former predominated in a ratio of about 91:9; this was shown by treatment of the mixture with benzophenone and nmr analysis of the resulting carbinolamines. The 8 derivative was isolated in 58% yield, suggesting a useful new route for the synthesis of *peri* compounds.  $\beta$ -Dimethylaminomethylnaphthalene was treated similarly to produce a mixture of the 3- and 1-lithioamines in a ratio of about 55:45; after treatment with benzophenone, the 2,3-disubstituted naphthalene compound was isolated in 25% yield. These lithioamine ratios were found not to change significantly over a wide range of lithiation times. Independent syntheses of three of the four carbinolamines indicated above were carried out and some further reactions of these compounds were effected.

Recently,<sup>2</sup> benzyldimethylamine (1) was lithiated with *n*-butyllithium in ether-hexane to form *o*-lithioamine 1', which was condensed with benzophenone to give carbinolamine 2. This product was converted to several derivatives.

In the present investigation, a similar study was made of  $\alpha$ - and  $\beta$ -dimethylaminomethylnaphthalenes which promised to be of special interest because of the possibility of lithiation at two nonequivalent positions in each case.

**Results with  $\alpha$ -Dimethylaminomethylnaphthalene (3).** This amine might conceivably undergo lithiation at either the 8 position to form lithioamine 3a' or the 2 position to form lithioamine 3b'; condensations of 3a' and 3b' with benzophenone would afford carbinolamines 4a and b, respectively (Scheme I).

This lithiation-condensation reaction was found to afford largely carbinolamine 4a, which was readily isolated in 58% yield. The crude reaction product, obtained in about 79% yield, was shown by thin layer chromatography (tlc) to consist not only of 4a but also of another component, presumably the isomeric carbinolamine 4b; evidence for 4b as the minor product is presented below. Actually, predominant *ortho* lithiation of 3 leading to 4b had been expected, since such *ortho* lithiation of amine 1 occurs exclusively.<sup>2,3</sup> The

<sup>a</sup> The solvent used was deuteriochloroform unless otherwise stated. <sup>b</sup> Downfield from tetramethylsilane (TMS) = 0 (internal standard). <sup>c</sup> Obtained by integration of peak areas; usually the reported value is the average of three integrations. The value in parentheses is the theoretical number of hydrogens, based on the proposed structure. <sup>d</sup> See ref 5. <sup>e</sup> Data for a 1-hr lithiation of amine 3; see Table III, entry two, for calculations based on this data. <sup>f</sup> Data for a 24-hr lithiation of amine 16; see Table IV, entry three, for calculations based on this data. <sup>g</sup> Run as a neat liquid.

with that of authentic carbinolamine 4a (see Table II). Thus, the methylene and N-methyl peaks observed in the spectrum of 4a were found also in that of the mixture. In addition, the latter spectrum showed two similar, but much smaller, peaks that may be ascribed to the same groups in 4b (see Table II). In support of these conclusions, the areas (by integration) of the methyl and methylene peaks assigned to 4b afforded a ratio of 3.1:1 (theoretical ratio, 3:1). Also, the total values of the integrations for each type of hydrogen in

the spectrum of the mixture afforded a ratio of 6:1.9:16.7 for methyl:methylene:aromatic<sup>5</sup> hydrogens (theoretical ratio, 6:2:17).

The relative amounts of isomeric carbinolamines **4a** and **b** in the mixture obtained according to Scheme I were estimated from the ratio of the integration values of their respective methyl (or methylene) peaks. Table III contains ratios of **4a** and **b** obtained in this manner from a series of experiments in which amine **3** was lithiated for various lengths of time followed by standardized periods for condensation with benzophenone and hydrolysis. These values show that the lithiation of amine **3** at the 8 position was favored over lithiation at the 2 position by about 91:9. The slight but steady increase in the amount of **4a** relative to lengths of reaction time may or may not be of significance. If a conversion of intermediate lithioamine **3b'** to lithioamine **3a'** occurs, it must do so very slowly, since the range of lithiation times employed was wide.

**Table III.** Reaction of Amine **3** According to Scheme I for Different Lithiation Times, Product Mixture Proportions by Nmr<sup>a</sup>

48 hr	52.7 <sup>h</sup>	11.5	92.0	8.0

<sup>a</sup> In all cases, three integrations were recorded and their average value was used for further calculations. <sup>b</sup> This ratio was obtained by dividing the average integration value for the methylene peak at 3.25 ppm by the average value for the methylene peak at 3.66 ppm. <sup>c</sup> This percentage was obtained by dividing the average integration value for the methylene peak at 3.25 ppm by the sum of the average values for both methylene peaks, and multiplying the resulting number by 100. <sup>d</sup> This percentage was obtained by subtracting the percentage obtained in <sup>c</sup> from 100. <sup>e</sup> In this experiment 53.8% of starting amine **3** was recovered by distillation. <sup>f</sup> See Table II, entry three, for additional data on this mixture. <sup>g</sup> In a similar experiment in which the *n*-butyllithium used was prepared in ether [see H. Gilman, J. Beel, C. Brannen, M. Bullock, G. Dunn, and L. Miller, *J. Am. Chem. Soc.*, **71**, 1499 (1949)], the total yield (**4a** + **4b**) was 85%, the ratio (**4a**:**4b**) was 9.5, and the percentage of **4a** was 90.3. <sup>h</sup> In this experiment 30.2% of starting amine **3** was recovered by distillation.

Further evidence that lithiation of amine **3** involved mainly the 8-hydrogen (*peri* hydrogen) was obtained by treatment of a lithiation mixture of **3a'** and **3b'** (after 24 hr) with deuterium oxide. The nmr spectrum of the resulting deuterated amine showed that the 8-hydrogen, which appears downfield from the rest of the aromatic hydrogens because of deshielding,<sup>6</sup> had been substituted by deuterium to the extent of 79%.

The highly preferential lithiation at the 8 position of amine **3** furnishes a new route to the synthesis of *peri* compounds, as illustrated by the condensation of the

(5) It is assumed that the peak for the hydroxyl hydrogen, which could be found nowhere else in the spectra of either the pure carbinolamines or their mixtures, is hidden within the aromatic multiplet; when deuteriochloroform solutions of these compounds were treated with deuterium oxide prior to analysis, the area of the aromatic portion of their spectra was reduced.

(6) For a discussion (and other examples) of such deshielding of the *peri* hydrogen of other 1-substituted naphthalenes see G. O. Dudek, *Spectrochim. Acta*, **19**, 697 (1963). We are indebted to Dr. P. W. Jeffs for help in the interpretation of our nmr data.

resulting lithioamine **3a'** with benzophenone to form carbinolamine **4a**. Presumably intermediate **3a'** could be condensed with other electrophilic compounds to form the corresponding *peri* products.

Moreover, such *peri* compounds may be converted to other 1,8 derivatives. For example, carbinolamine **4a** was converted to its methiodide **9**, which was cyclized by means of sodium amide to cyclic ether **11** in 89% yield (Scheme III).

**Scheme III**

The structure of **11** was supported by analysis and by infrared and nmr spectra (see Tables I and II). Also **11** was converted to lactone **12**, which was independently synthesized from anhydride **5** by a known method<sup>7</sup> (Scheme IV).

**Scheme IV**

Although the selenium dioxide oxidation of ether **11** afforded lactone **12** in only 11% yield, no other product was isolated; probably the yield of **12** from **11** could be improved. Attempts to reduce lactone **12** back to ether **11** with lithium aluminum hydride in ethyl ether were unsuccessful; instead of **11**, an acetal was obtained on recrystallization from ethanol. A similar observation has previously been reported.<sup>8</sup>

Interestingly, the preferential lithiation at the 8 position of  $\alpha$ -dimethylaminomethylnaphthalene **3** is to be contrasted with the previously observed<sup>9,10</sup> preferential lithiation at the 2 position of  $\alpha$ -methoxynaphthalene **13**.<sup>11</sup> Thus, lithiation of **13**, followed by carbonation, has afforded much more of acid **14** than acid **15**; the ratio of **14** to **15** was 83:17 with commercial *n*-butyllithium in hexane but 65:35 with the reagent prepared in ether.<sup>9a</sup> Incidentally, we observed no appreciable

(7) G. Wittig, M. Leo, and W. Wiemer, *Ber.*, **64**, 2410 (1931).

(8) R. L. Letsinger and P. T. Lansbury, *J. Am. Chem. Soc.*, **81**, 939 (1959).

(9) (a) B. M. Graybill and D. A. Shirley, *J. Org. Chem.*, **31**, 1221 (1966); (b) S. V. Sunthakar and H. Gilman, *ibid.*, **16**, 8 (1951).

(10) R. A. Barnes and L. J. Nehmsmann (*ibid.*, **27**, 1939 (1962)) proposed that, initially, 8-lithio-1-methoxynaphthalene was formed predominantly, followed by isomerization to 2-lithio-1-methoxynaphthalene; later work<sup>9a</sup> presented evidence that such a change is negligible.

(11) The reason for this difference and the mechanism of the lithiation of these compounds are under investigation.

difference in lithiations of amine 3 under these two conditions (see Table III, footnote g).

**Results with  $\beta$ -Dimethylaminomethylnaphthalene (16).** This amine might undergo lithiation at either the 3 position to form lithioamine 16a' or the 1 position to form lithioamine 16b'; condensations of 16a' and 16b' with benzophenone would afford carbinolamines 17a and b, respectively (Scheme V).

Scheme V

Actually, the crude condensation product, obtained in 79% yield, was shown by tlc to consist of two components, one of which was isolated in 25% yield by fractional crystallization. That the compound thus isolated was 17a was supported by analysis and by infrared and nmr spectra (see Tables I and II); its structure was confirmed by independent synthesis from amino acid 18 through the known bromo acid 19 (Scheme VI).

Scheme VI

Bromo acid 19 agreed with its previously reported description.<sup>12</sup> The structures of intermediate bromo amide 20 and bromo amine 21 were supported by analysis and absorption spectra (see Tables I and II). The over-all yield of carbinolamine 17a from amino acid 18 was 20%, which is lower than that (25%) obtained by the much easier method shown in Scheme V.

Although carbinolamine 17b was not isolated from the reaction mixture obtained according to Scheme V, it was shown to be present by comparison of the nmr spectrum of this mixture with those of independently synthesized samples of 17a (Scheme VI) and 17b; the latter was prepared from 22 through the known dibromide 23 (Scheme VII). Clearly the peaks exhibited by 17a and 17b accounted fully for those shown by the mixture (see Table II).

Scheme VII

Dibromide 23 agreed with its previously reported description.<sup>13</sup> The structure of bromo amine 24 was supported by analysis and by infrared and nmr spectra (see Tables I and II). The over-all yield of carbinolamine 17b from bromide 22 was 46%.

The relative amounts of isomeric carbinolamines 17a and 17b in the mixture obtained according to Scheme V were estimated from the ratio of the integration values for their respective methylene peaks. Table IV contains ratios of 17a and b obtained in this manner for a series of experiments in which amine 16 was lithiated for various lengths of time followed by standardized periods for

Table IV. Reaction of Amine 16 According to Scheme V for Different Lithiation Times, Product Mixture Proportions by Nmr<sup>a</sup>

ation with benzophenone and hydrolysis. values show that the lithiation of amine 16 at position was favored over lithiation at the 1 position about 55:45. The slight but steady increase in amount of 17a relative to lengths of reaction time may not be of significance.

preferential lithiation of amine 16 at the 3 position furnishes an easy route to the synthesis of 2,3-substituted naphthalene compounds, as illustrated by the condensation of lithioamine 16a' with benzophenone to form 17a. Presumably intermediate 16a' could be condensed with other electrophilic compounds to afford other 2,3-substituted naphthalenes.

Moreover, such 2,3-substituted naphthalenes may be converted to other 2,3 derivatives. Thus, carbinolamine 17a was converted to its methiodide which was then converted by means of excess potassium amide to amine 25 in 70% yield.<sup>14</sup> The structure of 25 is supported by analysis and by infrared and nmr (see Tables I and II). Also, 17a was treated with hydrobromic acid to form apparently quaternary ammonium salt 195% yield.

In connection with this work, carbinolamine 17b (Scheme VII) was converted to its methiodide 27, which was thermally cyclized to naphthofuran 28 by a previously developed in this laboratory.<sup>15</sup> The structure of cyclic ether 28 was supported by analysis and by infrared and nmr spectra (see Tables I and

comparative lithiation at the 3 position of amine comparable to that at the 3 position of  $\beta$ -methoxy-naphthalene 29 observed previously.<sup>9b</sup> The latter was evidenced by carbonation to form methoxy naphthalene 31 in 50% yield; none of the isomeric acid 31 was observed.<sup>9b</sup>

We have observed that lithiation of methoxy compound 29 with *n*-butyllithium in ether-hexane appears to give a mixture of lithio intermediates, since treatment with benzophenone afforded two products (by

## Experimental Section

Melting points, taken on a Thomas-Hoover capillary melting point apparatus, are uncorrected. Infrared spectra were recorded on a Perkin-Elmer Model 137 Infracord. Solids were prepared as potassium bromide pellets and liquids were run neat between sodium chloride plates. Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer using deuteriochloroform solutions and tetramethylsilane as an internal standard. These spectra were integrated three times and the average value used to calculate the relative number of hydrogens associated with each peak. Thin layer chromatographic (tlc) analyses were performed on microscope slides covered with a thin layer of Silica Gel G (Merck). Chloroform solutions of the material to be tested were spotted onto the plates, which were eluted with benzene and subsequently developed by standing in a jar containing crushed iodine crystals. Elemental analyses were performed by Paul Demoen, Janssen Pharmaceutical Research Laboratories, Beerse, Belgium.

**$\alpha$ -Dimethylaminomethylnaphthalene (3).** A solution of 500 g (2.83 moles) of 1-chloromethylnaphthalene and 550 g (12.2 moles) of anhydrous dimethylamine in 4 l. of absolute ethanol was stirred magnetically in a tightly stoppered flask at room temperature for 1 week. The solvent was removed, and the residue was stirred with excess 6 *M* sodium hydroxide and ether. The layers were separated. The alkaline aqueous layer was extracted with ether and the ethereal extracts were combined with the original ether layer. This ether solution was extracted with 3 *M* hydrochloric acid, and the acidic extracts were then made strongly alkaline. The resulting mixture was shaken with ether, and the layers were separated. The ether layer was dried over anhydrous magnesium sulfate, and the solvent was removed. The residual oil was distilled to give 475 g (91%) of  $\alpha$ -dimethylaminomethylnaphthalene (3), bp 98–103° (0.5 mm) [lit.<sup>16</sup> bp 148–152° (16 mm)]. The picrate, after several recrystallizations from 95% ethanol, melted at 144–146° (lit.<sup>16</sup> mp 145°).

**Lithiation of Amine 3 and Condensation with Benzophenone.** In Table III are summarized the total yields and the estimated ratios of carbinolamines 4a and b obtained after various lithiation times. A typical experiment is described below.

To a stirred solution of 4.63 g (0.025 mole) of  $\alpha$ -dimethylaminomethylnaphthalene (3) in 200 ml of dry ether was added 17.7 ml (0.0275 mole) of 1.55 *M* *n*-butyllithium in hexane<sup>17</sup> to form lithioamines 3a' and 3b' (see Scheme I). The mixture was stirred magnetically in a tightly stoppered flask for 24 hr. The resulting dark red solution was added cautiously to a solution of benzophenone in 50–75 ml of dry ether, which had been brought to reflux on a steam bath. The resulting blue solution was refluxed on the steam bath for about 5 min, the volume being reduced to about 100 ml. The flask was then tightly stoppered and the solution was stirred magnetically for 12 hr to produce a precipitate. The reaction mixture was hydrolyzed with 100 ml of water, stirred for 12 hr, and filtered. The solid was washed with water and a little cold ether and dried to give 6.58 g of a mixture of carbinolamines 4a and b, mp 190–197°. The layers of the filtrate were separated. The ethereal layer was combined with three ethereal extracts of the aqueous layer. This ether solution was extracted three times with 1 *M* hydrochloric acid, and the combined acidic extracts were made strongly alkaline with 6 *M* sodium hydroxide. The resulting mixture was extracted three times with ether and the combined ethereal extract was dried over anhydrous magnesium sulfate. The solvent was removed and the residue was recrystallized from hexane to give 0.72 g of a mixture of carbinolamines 4a and b, mp 150–190°; total yield, 7.30 g (79.4%).

This product mixture was crushed and mixed well in a mortar. A sample was dissolved in deuteriochloroform for nmr analysis. The data for a similar case are listed in Table II, entry three, and the calculations based on these data are listed in Table III, entry two.

From a similar reaction (larger scale), in which the lithiation time was 48 hr, 13.55 g (73.7%) of a mixture of 4a and b was obtained. One recrystallization from acetonitrile afforded 10.72 g (58.3%) of pure 1-dimethylaminomethyl-8-diphenylhydroxymethylnaphthalene (4a), mp 198–201°, and 200–201° after further recrystallization from this solvent.

*Anal.* Calcd for  $C_{26}H_{25}NO$ : C, 85.00; H, 6.85; N, 3.82. Found: C, 85.32; H, 6.69; N, 4.05.

**Independent Synthesis of Carbinolamine 4a.** 1,8-Naphthalic anhydride (5) was converted in 55% yield to 8-bromo-1-naphthoic (6), mp 177–179° (lit.<sup>4</sup> mp 177–178°), as described previously.<sup>4</sup>

A solution of 25.15 g (0.10 mole) of bromo acid 6 in 60 ml of dry diglyme<sup>18</sup> was added slowly to a stirred suspension of 3.5 g (0.093 mole) of sodium borohydride in 40 ml of dry diglyme<sup>18</sup> under a positive nitrogen pressure, followed by a solution of 24.5 g (0.12 mole) of freshly distilled boron trifluoride etherate in 25 ml of dry diglyme,<sup>19</sup> essentially as described previously for a similar reduction.<sup>19</sup> After stirring for 8 hr, the thick white suspension was poured onto ice (1500 ml) and 3 M hydrochloric acid (100 ml). After the ice had melted, the cold suspension was filtered, and the solid obtained was treated with sodium bicarbonate solution to remove 2.18 g (3.7%) of bromo acid 6, mp 176–178.5°. The bicarbonate-insoluble material was boiled with 100 ml of hexane, and the mixture was filtered; this treatment was repeated several times, and the combined filtrates were concentrated to afford 16.0 g (67%) of 8-bromo-1-naphthylmethanol (7), mp 86–88°, and 87–88.5° after several more recrystallizations from hexane.

*Anal.* Calcd for  $C_{11}H_9BrO$ : C, 55.72; H, 3.82; Br, 33.71. Found: C, 55.78; H, 3.79; Br, 33.92.

The phenylurethan, recrystallized from benzene, melted at 140–141°.

*Anal.* Calcd for  $C_{19}H_{11}BrNO_2$ : N, 3.93; Br, 22.43. Found: N, 4.04; Br, 22.32.

To a solution of 14.5 g (0.06 mole) of bromocarinol 7 in 500 ml of dry ether at –80° was added 10.8 g (0.04 mole) of phosphorus tribromide; the mixture was stirred at room temperature for 7 hr. Work-up afforded the crude dibromide (white solid), which was dissolved in 700 ml of absolute ethanol and treated with 25 ml of anhydrous dimethylamine. After stirring in a tightly stoppered flask for 24 hr, the mixture was processed as described above for the preparation of 3. Distillation of a portion of the yellow oil obtained seemed to cause decomposition, so the remaining portion was chromatographed on alumina, eluting with dry ether. The colorless oil obtained by this process was magnetically stirred *in vacuo* (1 mm) for 30 min to afford 12.23 g (75%) of 8-bromo-1-dimethylaminomethylnaphthalene (8). This colorless oil was used for spectral samples and for the further reactions described below. The picrate of 8, recrystallized three times for 95% ethanol, melted at 187–188°.

*Anal.* Calcd for  $C_{19}H_{17}BrN_2O_7$ : C, 46.27; H, 3.47; N, 11.36; Br, 16.21. Found: C, 46.22; H, 3.60; N, 11.66; Br, 16.48.

A stirred solution of 4.5 g (0.017 mole) of bromo amine 8 in 100 of dry ether was treated with 16.5 ml (0.026 mole) of 1.55 M *n*-butyllithium in hexane.<sup>17</sup> The clear orange-red solution was stirred for 60 min in a stoppered flask and then poured cautiously into a refluxing solution of 4.97 g (0.027 mole) of benzophenone in 100 ml of dry ether. After refluxing for 1 min, the flask was stoppered, and the solution was stirred for 6 hr. The resulting suspension was hydrolyzed with 100 ml of water and processed as described above for the lithiation of amine 3 to give 4.76 g (76.3%) of carbinolamine 4a, mp 198–200°, undepressed on admixture with a sample of 4a prepared from 3. The infrared spectra of the two samples of 4a were identical.

**Preparation of Methiodide 9.** A solution of 9.19 g (0.025 mole) of carbinolamine 4a in 25 ml of methyl iodide was refluxed for 3 hr. Evaporation of the excess methyl iodide afforded 12.56 g (98.4%) of 1-(8-diphenylhydroxymethyl)naphthylmethyltrimethylammonium iodide (9), mp 213.5–215°, and 212–213° after precipitation from an acetonitrile solution with ether.

*Anal.* Calcd for  $C_{27}H_{31}INO$ : C, 63.65; H, 5.54; N, 2.75. Found: C, 63.34; H, 5.50; N, 2.80.

**Cyclization of Methiodide 9 to Ether 11.** To a stirred suspension of 26 g (0.051 mole) of methiodide 9 in 600 ml of commercial anhydrous liquid ammonia was added, during 5 min, a solution of 0.054 mole of sodium amide in 150 ml of liquid ammonia.<sup>20</sup> After 1 hr, the ammonia was replaced with 500 ml of dry ether (steam bath), and the resulting suspension was shaken with 150 ml of water. Filtration afforded 8.35 g of 1,1-diphenyl-3H-naphtho[1,8-*cd*]pyran (11), mp 158–160°. The ether layer of the filtrate was separated and washed with dilute hydrochloric acid, followed by dilute sodium hydroxide. After drying over anhydrous magnesium sulfate, the solvent was removed to afford 6.40 g more of 11, mp 158–160°;

total yield 14.74 g (89%). Several recrystallizations from ethanol failed to raise the melting point.

*Anal.* Calcd for  $C_{24}H_{18}O$ : C, 89.41; H, 5.63. Found: C, 89.12; H, 5.76.

**Oxidation of cyclic ether 11** was effected by heating a 1.0-g (0.0031 mole) sample with 0.5 g (0.0045 mole) of selenium dioxide at 180° for 30 min, then at 150–160° for 2.5 hr (Woods metal bath). After cooling the solid was crushed under dry ether, and the mixture was filtered. The ethereal filtrate was washed with water and dried over anhydrous magnesium sulfate. The solvent was removed to afford 0.30 g of a solid, mp 170–190°. Two recrystallizations from absolute ethanol gave 0.11 g (11%) of 1,1-diphenyl-3-oxonaphtho[1,8-*cd*]pyran (12), mp 200–202.5°. Two more recrystallizations raised the melting point to 203–205° (lit.<sup>7</sup> mp 203–205°), undepressed on admixture with authentic lactone 12 (mp 204–205.5°) prepared from anhydride 5 and phenyllithium.<sup>7</sup> The infrared spectra of the two samples of 12 were identical.

**Attempted reduction of lactone 12** (prepared from 5 by Wittig's method)<sup>7</sup> with lithium aluminum hydride in dry ether employing a Soxhlet extractor<sup>21</sup> afforded, after treatment with absolute ethanol, apparently 1,1-diphenyl-3-ethoxynaphtho[1,8-*cd*]pyran, mp 196–198°, and 198.5–201° after several more recrystallizations from absolute ethanol (lit.<sup>4</sup> mp 197.5–198.5°). The yield was 76%.

**$\beta$ -Dimethylaminomethylnaphthalene (16).** 2-Chloromethylnaphthalene, bp 102–108° (0.8 mm) [lit.<sup>22</sup> bp 125–132° (2 mm)], was prepared in 64% yield from 2-naphthoic acid as described previously.<sup>22</sup>

A solution of 32.6 g (0.185 mole) of this chloride and 100 ml (1.51 moles) of anhydrous dimethylamine in 300 ml of absolute ethanol was allowed to stand in a tightly stoppered flask in an ice-salt bath (dewar) for several days. The reaction mixture was then processed as described above for the preparation of amine 3 to give 23.1 g (67.4%) of  $\beta$ -dimethylaminomethylnaphthalene (16), bp 89–91° (0.45 mm) [lit.<sup>18</sup> bp 130–132° (14 mm)]. The picrate of 16, recrystallized from 95% ethanol, melted at 151–152° (lit.<sup>18</sup> mp 152°).

**Lithiation of Amine 16 and Condensation with Benzophenone.** In Table IV are summarized the total yields and the estimated ratios of carbinolamines 17a and 17b obtained after various lithiation times. A typical experiment is described below.

To a stirred solution of 4.63 g (0.025 mole) of  $\beta$ -dimethylaminomethylnaphthalene (16) in 200 ml of dry ether was added 17.7 ml (0.0275 mole) of 1.55 M *n*-butyllithium in hexane<sup>17</sup> to form lithioamines 16a' and 16b' (Scheme V). The mixture was stirred magnetically in a tightly stoppered flask to produce a dark red suspension containing an orange precipitate. This suspension was added to benzophenone and processed as described above for the lithiation of amine 3 to give 7.19 g (78.3%) of a mixture of 17a and b, mp 142–178°. A sample was prepared for nmr analysis as there described; the resulting data for this experiment are listed in Table II, entry three, while calculations based on these data may be found in Table IV, entry three.

From a similar reaction (larger scale), in which the lithiation time was 45 hr, 19.04 g (76.4%) of a mixture of 17a and b was obtained. This product was refluxed with 500 ml of acetonitrile; after filtering, the solution was allowed to stand undisturbed overnight. The precipitated crystals were filtered and the process was repeated. Filtration afforded 6.3 g (25.3%) of pure 2-dimethylaminomethyl-3-diphenylhydroxymethylnaphthalene (17a), mp 194–197°. The analytical sample of 17a, isolated similarly, but recrystallized twice from acetonitrile and once each from ligroin and hexane, melted at 193–194.5°.

*Anal.* Calcd for  $C_{25}H_{23}NO$ : C, 85.00; H, 6.85; N, 3.82. Found: C, 84.87; H, 6.96; N, 3.72.

**Independent Synthesis of Carbinolamine 17a.** Amino acid<sup>23</sup> 18 was converted in 65% yield to 3-bromo-2-naphthoic acid (19), mp 216–218.5° (lit.<sup>13</sup> mp 219–220°), as described previously.<sup>13</sup>

A solution of 15.86 g (0.063 mole) of bromo acid 19 and 50 ml of thionyl chloride in 50 ml of dry benzene was refluxed for 30 min. After removing the excess thionyl chloride and benzene, the residue was cooled and dissolved in 100 ml of methylene chloride. This solution was added to a cold suspension of 50 ml of dimethylamine and 250 ml of 1 M sodium hydroxide. After stirring for 3 hr, the

re was heated until the temperature of the escaping vapors reached 80°, then cooled and extracted with ether. The ethereal extract was washed with dilute acid and alkali and dried. The extract was removed to give a red liquid, which solidified *in vacuo*. The residue was boiled with 1 l. of water and the mixture filtered; the filtrate was cooled to deposit N,N-dimethyl-3-bromo-2-naphthylamine (20). This treatment was repeated several times with the dried material to give a total of 12.0 g (68.2%) of 20, mp 112–115°, 14–115° after another recrystallization from boiling water.

*Anal.* Calcd for  $C_{14}H_{12}BrNO$ : C, 56.21; H, 4.35; N, 5.03. Found: C, 55.94; H, 4.34; N, 5.10.

A solution of 6.2 g (0.022 mole) of bromo amide 20 in 50 ml of tetrahydrofuran (THF) was reduced with 66 ml (0.066 mole) of a solution of diborane in THF<sup>14</sup> essentially as described previously for similar amides.<sup>24</sup> After stirring for 1 hr at room temperature and for another hour at reflux, the reaction mixture was cooled and hydrolyzed, first with water dropwise (caution, exothermic) and then with 50 ml of 6 *M* hydrochloric acid. The solution was distilled until the temperature of the vapor reached 90°, the residual mixture was cooled and extracted with ether. The ether extract was removed from the dried ethereal solution and the residue was distilled to afford 3.69 g (63%) of 3-bromo-2-dimethylaminomethylnaphthalene (21), bp 82–83° (0.03 mm).

*Anal.* Calcd for  $C_{14}H_{14}BrN$ : C, 59.10; H, 5.36; N, 5.32. Found: C, 58.88; H, 5.41; N, 5.21.

The picrate, recrystallized several times from 95% ethanol, melted at 172–173.5°.

*Anal.* Calcd for  $C_{14}H_{17}BrN_2O_7$ : N, 11.37. Found: N, 11.71. A stirred solution of 2.0 g (0.0076 mole) of bromo amine 21 in 100 ml of dry ether was treated with 7.3 ml of *n*-butyllithium in ether<sup>17</sup> to produce an amber-colored suspension. After stirring magnetically for 75 min, this suspension was added to a refluxing solution of 2.21 g (0.012 mole) of benzophenone in dry ether and processed as described above for the similar reaction of bromo amine 8 to give 2.05 g (73.7%) of carbinolamine 17a, mp 192–196°, processed on admixture with a sample of 17a prepared as described above. The infrared spectra of the two samples of 17a were identical.

**10-Substitution Rearrangement of Methiodide of Carbinolamine 17a.** A solution of 7.65 g (0.021 mole) of carbinolamine 17a in 100 ml of methyl iodide was refluxed for 36 hr. The resulting solid was collected to give 8.13 g (77%) of, presumably, 2-(3-phenylhydroxymethyl)naphthylmethyltrimethylammonium iodide, mp 195–196° (temperature raised from 100°). Evaporation of the filtrate afforded some (20%) of the starting carbinolamine.

A sample of unrecrystallized methiodide of 17a (6.0 g, 0.0118 mole) was added to a stirred solution of 0.05 mole of potassium amide in 500 ml of commercial anhydrous liquid ammonia. After 4 hr, the mixture was neutralized with ammonium chloride and processed as described previously<sup>14</sup> for the reaction of the methiodide of the related carbinolamine 2. There was obtained, on recrystallization of the product from hexane, 3.13 g (70%) of 1-dimethylaminomethyl-2-methyl-3-diphenylhydroxymethylnaphthalene, mp 126–129°, and 126–128° after several more recrystallizations from this solvent.

*Anal.* Calcd for  $C_{27}H_{27}NO$ : C, 85.01; H, 7.13; N, 3.67. Found: C, 85.02; H, 7.05; N, 3.73.

**Cyclization of Carbinolamine 17a.** This compound (0.75 g, 0.002 mole) was refluxed with 25 ml of hydrobromic acid for 6 hr. The resulting solid was collected and washed with small portions of water and dry ether to give 0.81 g (92%) of apparently 2,2-dimethyl-3,3-diphenylbenz[*f*]isoindolinium bromide (26), mp 288–290°, and 299–300° after recrystallization from acetonitrile.

*Anal.* Calcd for  $C_{24}H_{24}BrN$ : C, 72.60; H, 5.62; N, 3.25. Found: C, 72.64; H, 5.73; N, 3.38.

**Independent Synthesis of Carbinolamine 17b.** A mixture of 53.4 g (0.242 mole) of 1-bromo-2-methylnaphthalene (22) and 49.1 g (0.273 mole) of *N*-bromosuccinimide (NBS) in 300 ml of dry carbon tetrachloride was stirred and refluxed (no catalyst was used) for 14 hr, essentially as described previously.<sup>13</sup> The product was recrystallized from ligroin to afford 48.80 g (67%) of 1-bromo-2-bromomethylnaphthalene (23), mp 105.5–107.5° (lit.<sup>13</sup> mp 107°).

A cold stirred solution of 88 g (0.293 mole) of dibromide 23 in 600 ml of absolute ethanol was treated with 53 g (1.18 moles) of anhydrous dimethylamine. After stirring and heating at 110° in a tightly stoppered flask for 20 hr, the reaction mixture was processed as described above for amine 3 to give 69.7 g (90%) of 1-bromo-2-dimethylaminomethylnaphthalene (24), bp 98° (0.14 mm).

*Anal.* Calcd for  $C_{14}H_{14}BrN$ : C, 59.10; H, 5.36; N, 5.32. Found: C, 59.29; H, 5.42; N, 5.65.

The picrate, recrystallized from 95% ethanol, melted at 142–143.5°.

*Anal.* Calcd for  $C_{14}H_{17}BrN_2O_7$ : C, 46.23; H, 3.47; N, 11.36. Found: C, 45.88; H, 3.57; N, 11.15.

To a stirred solution of 13.31 g (0.05 mole) of bromo amine 24 in 200 ml of dry ether was rapidly added 38 ml (0.059 mole) of 1.55 *M* *n*-butyllithium in hexane.<sup>17</sup> After stirring magnetically in the tightly stoppered flask for 70 min, the solution was added to a refluxing solution of 12.4 g (0.068 mole) of benzophenone in dry ether and processed as described above, for the similar reaction of bromo amine 8, to give 14.05 g (76.5%) of 1-diphenylhydroxymethyl-2-dimethylaminomethylnaphthalene (17b), mp 160–162°. Several more recrystallizations from hexane failed to raise the melting point.

*Anal.* Calcd for  $C_{24}H_{24}NO$ : C, 85.00; H, 6.85; N, 3.80. Found: C, 84.94; H, 6.69; N, 3.93.

**Thermal Cyclization of Methiodide 27 to Cyclic Ether 28.** A solution of 3.67 g (0.01 mole) of carbinolamine 17b in 25 ml of methyl iodide was refluxed for 7 hr, and the excess methyl iodide was evaporated. The solid residue was dissolved in refluxing acetonitrile and the solution allowed to cool while 500 ml of dry ether was added dropwise. The cold suspension was filtered to afford 4.21 g (82.6%) of 2-(1-diphenylhydroxymethyl)naphthylmethyltrimethylammonium iodide (27), mp 204–206°. This melting point was not raised by several more such treatments.

*Anal.* Calcd for  $C_{27}H_{28}INO$ : C, 63.65; H, 5.54; N, 2.75. Found: C, 63.36; H, 5.50; N, 3.00.

A 3.69-g (0.0073 mole) sample of methiodide 27 was heated at 210–220° (Woods metal bath) for 15 min under dry nitrogen. After cooling, the solid was processed as described previously<sup>14</sup> for the related cyclization of the methiodide of 2. Recrystallization of the product afforded 1.87 g (80%) of 1,1-diphenyl-1,3-dihydronaphtho[1,2-*c*]furan (28), mp 156–158°, and 157–158.5° after several recrystallizations from hexane.

*Anal.* Calcd for  $C_{24}H_{18}O$ : C, 89.41; H, 5.63. Found: C, 89.04; H, 5.63.

# The Chemistry of Metallocenes. I. Carbonium Ion Stabilization by the Ferrocenyl Group<sup>1,2</sup>

T. G. Traylor and J. C. Ware

Contribution from the Department of Chemistry, Revelle College, University of California at San Diego, La Jolla, California. Received July 8, 1966

**Abstract:** The rapid solvolyses of  $\alpha$ -ferrocenylcarbonyl derivatives,  $\text{FerCR}_2\text{X}$ , have been accurately correlated with carbonyl stretching frequencies of  $\text{FerCOCH}_3$ ,  $\text{ArCOCH}_3$ ,  $\text{FerArCOCH}_3$ , and with  $\sigma^+$  values. These correlations are interpreted as evidence that the main contribution of the iron atom to the  $\text{FerC}^+\text{R}_2$  stability is hyperconjugation ( $\sigma$ - $\pi$  conjugation). The  $\sigma^+$  values for the ferrocenyl (Fer) group have been determined:  $\sigma^+_{\alpha\text{-Fer}} = -1.35$ ,  $\sigma^+_{p\text{-Fer}} = -0.71$ , and  $\sigma^+_{m\text{-Fer}} = 0$ . Reactivities of metallocenes are discussed in terms of breaking and making the metal-carbon bond in a step analogous to  $\text{S}_\text{E}2$  reactions. The presence of filled d orbitals in the metal is suggested to influence reactivities by their influence on cyclopentadienide-metal bonding rather than by direct interaction with electrophilic reagents. The terminology applied to the effects of  $\beta$  substituents on solvolysis reactions and mechanisms of such effects is reviewed.

The  $\alpha$ -ferrocenylcarbonium ions I generated by solvolyses<sup>3,4</sup> or protonation of vinylferrocenes<sup>5</sup>

have about the same stability as  $\alpha$ -methoxymethyl II<sup>4</sup> or triphenylmethyl III<sup>4</sup> cations and react with high stereospecificity with nucleophiles.<sup>3b,4a</sup>

A molecular orbital description of I incorporating both direct backside participation of iron orbitals and delocalization into the ring has been formulated by Hill and Richards<sup>3b</sup> to explain the observed reactivity and stereospecificity of reaction 1.

A comparison of this reaction with reactions of other  $\beta$ -metalloalkyl derivatives<sup>6</sup> and a consideration of the ease of oxidation of ferrocene<sup>7a</sup> suggest that iron

hyperconjugation ( $\sigma$ - $\pi$  conjugation) might be exceptionally facile.

This phenomenon may also explain the observed rate acceleration and stereochemistry but can be differentiated from neighboring nucleophilic participation in several ways. In this paper we describe and document methods for differentiating these two effects and then use these methods to indicate the nature of the stabilization provided by the ferrocenyl group.

## Results

We have employed four experimental methods to test whether a substituent accelerates  $\text{S}_\text{N}1$  reactions by neighboring nucleophilic attack or by  $\sigma$  delocalization (including hyperconjugative or  $\sigma$ - $\pi$  delocalization). Two of these tests are well documented in the published literature and will be discussed below. We offer the following evidence for the other two.

**Internal Nucleophilic Attack at the *para* Position in Benzyl Chlorides.** It seems reasonable that a group which accelerates  $\text{S}_\text{N}1$  solvolysis by neighboring nucleophilic attack

will not show this accelerating effect in the *para* position of a benzyl derivative because the aromaticity would then be lost.

In order to determine whether such *para*-nucleophilic attack occurs to a significant extent we have studied the effect of one of the best neighboring groups ( $\text{EtS}$ ) on benzyl chloride solvolysis as shown below.

*p*-Ethylthiomethylbenzyl chloride (IV) was synthesized by the reaction of the sodium salt of ethanethiol with a fourfold excess of *p*-xylylene dichloride. The rates of solvolysis of benzyl chloride and the substituted chloride IV in 50% aqueous dioxane were determined conductometrically. The rate constants at 80.0° were  $5.90 \times 10^{-5} \text{ sec}^{-1}$  for benzyl chloride and  $8.70 \times 10^{-5} \text{ sec}^{-1}$  for IV. This indicates no appreciable acceleration in benzyl chloride solvolysis by nucleophilic participation in the *para* position.<sup>8</sup>

**Carbonyl Stretching Frequencies.** The rates of solvolyses of alkyl tosylates  $\text{R}_1\text{CHOTos}$  have been quantitatively correlated with carbonyl stretching frequencies in  $\text{R}_1\text{C}=\text{O}$ .<sup>9</sup> Similarly the solvolyses of aralkyl chlorides<sup>10</sup>  $\text{ArCHClCH}_3$  may be correlated with  $\text{ArCOCH}_3$  stretching frequencies<sup>11-13</sup> because both correlate with  $\sigma^+$ . It has been shown that, although neighboring groups may accelerate  $\text{S}_{\text{N}}1$  solvolysis, such groups do not make a corresponding change in carbonyl stretching frequencies of the ketones.<sup>9</sup> In order to have a consistent set of carbonyl stretching frequen-

cies of acetophenones with which to compare the ferrocenyl derivatives we have remeasured a large number of such frequencies. The data, along with those for the ferrocenyl-substituted ketones, are shown in Table I. A plot of  $\nu_{\text{C}=\text{O}}$  vs. known  $\sigma^+$  values appears in Figure 1 where previously unknown  $\sigma^+$  values are assigned from the measured  $\nu_{\text{C}=\text{O}}$ . The carbonyl stretching frequencies reported here are in good agreement with those of Jones, Forbes, and Mueller.<sup>12</sup> The correlation for *para* derivatives is excellent, while that for *meta* derivatives is less satisfactory. It may be that the latter should be correlated by a line of greater slope. The  $\sigma^+$  values can be calculated from the equation

$$\sigma^+ = 0.0877(\nu_{\text{C}=\text{O}} - 1691.1) \quad (5)$$

Because these frequencies can now be measured to an accuracy of  $\pm 0.5 \text{ cm}^{-1}$ , the maximum error in  $\sigma^+$  will be  $\pm 0.044$ . This equation should make possible the determination of  $\sigma^+_a$  for a variety of other aromatic systems ( $\sigma^+_a$  is defined as the  $\sigma^+$  constant for the group at the position of reaction. Thus  $\sigma^+_{a-\text{Ph}} \equiv 0 \equiv \sigma^+_{p-\text{H}}$ . Therefore  $\sigma^+_a$  includes Brown's  $\sigma^+$  constants<sup>14</sup> and is equivalent to the  $\sigma_r$  and " $\sigma$ " constants referred to by Streitwieser.<sup>15</sup>

The correlation of solvolysis rates (see below) with corresponding ketone carbonyl frequencies for  $\alpha$ -phenethyl chlorides is shown in Figure 2. The equation of the line may be written  $\log k = 0.64(\nu_{\text{C}=\text{O}} - 1691)$ , as contrasted with  $\log k = 0.132(\nu_{\text{C}=\text{O}} - 1720)$  found by Foote<sup>9a</sup> for aliphatic systems. Obviously a single line will not correlate both aralkyl and alkyl derivatives. In addition the correlation of  $\nu_{\text{C}=\text{O}}$  for  $\text{RCOCH}_3$  with  $\sigma^+$ , of the very electronegative R groups F, Cl, Br,  $\text{NH}_2$ ,  $\text{CH}_2\text{O}$ ,  $\text{C}_6\text{H}_5\text{O}$  (attached directly to the carbonyl) is very poor and has a slope which reflects a very strong inductive effect on  $\nu_{\text{C}=\text{O}}$ . Therefore, we have omitted such groups<sup>16,17</sup> (as well as R = alkyl) from our plots of  $\nu_{\text{C}=\text{O}}$  vs.  $\sigma^+$ . Each of these correlations appears to be limited to a narrow range of inductive effects. The inclusion of ferrocenyl with the aromatic series in our treatment seems justified, since it is aromatic and has an inductive effect<sup>7a</sup> within the range covered by the  $\alpha$  substituents treated in Figures 1 and 2.

**Syntheses.** The phenylferrocenes employed in this study were synthesized by treating acetylbenzene-diazonium salts with ferrocene,<sup>7b</sup> reducing the ketones, and treating the resulting alcohols with concentrated hydrochloric acid or dry hydrogen chloride.

The analyses and nmr spectra of the intermediate products and the final chlorides are definitive for structure

(16) A referee has suggested that the omission of the MeO group from Figure 1 invalidates the treatment for the ferrocenyl group. The omission of aromatic or electronegative groups in the treatment of Foote<sup>9a</sup> do not, in our opinion, invalidate the correlations (see ref 17).

(17) Although inductive effects appear to dominate in the carbonyl stretching frequencies of  $\text{RCOCH}_3$  for MeO, Cl, etc., inductive destabilization of carbonium ions by MeO is seen to be negligibly small by the following comparison. Whereas we would calculate from eq 14 (using  $\tau$ ) that  $\sigma^+_{p-\text{alkyl}}$ ,  $\sigma^+_{p-\text{MeO}}$ , and  $\sigma^+_{a-\text{MeO}}$  should be in the ratio  $-0.35$ ,  $-0.70$ , and  $-1.4$ , the observed values are  $-0.35$ ,  $-0.78$ , and  $-1.4$ , in good agreement: T. Inukai, *Bull. Chem. Soc. Japan*, **35**, 400 (1962).

(8) We also showed that *p*-hydroxymethylbenzyl chloride reacts with ethoxide ion at the same rate as does benzyl chloride, but this finding is not conclusive to the point due to the ease of  $\text{S}_{\text{N}}2$  displacement on benzyl chloride.

## Discussion

**Effects of  $\beta$  Substituents on Solvolysis Reactions.** Before discussing in detail the effects of  $\beta$ -metal substitution on solvolysis reactions, we wish to reconsider the various phenomena attributed to the effects of  $\beta$  substituents upon the stabilities of developing carbonium ions.

The terms "hyperconjugation,"<sup>21</sup> "elimination,"<sup>22</sup> "fragmentation,"<sup>23</sup> and " $\sigma$ - $\pi$  conjugation,"<sup>24</sup> have been applied to processes in which a carbonium ion is stabilized by  $\pi$  conjugation with an orbital previously bonding to another atom<sup>25</sup> (see VI). The names "neighboring group participation,"<sup>26b</sup> "anchimeric assistance,"<sup>26</sup>

or "synartetic acceleration"<sup>27</sup> are used to designate stabilization of a carbonium ion by direct bonding to a neighboring atom as in VII or VIII. In most calculations of anchimeric assistance (or bridged ion stabilities)<sup>26c,28</sup> some  $\pi$  bonding of the type VI is included, and the structure generally written is VIII. There is thus some ambiguity in these terms and we believe that this ambiguity has contributed to the controversy concerning the nature and extent of occurrence of such processes.<sup>29</sup>

In this discussion we will consider one extreme, VI, in which the groups G can form stable cations ( $G = \text{R}_2\text{NCH}_2$ ,  $\text{C}_7\text{H}_7$ , Li,  $\text{MgX}$ , etc.), and another extreme, VII, in which the G is a poor cation but a rather good nucleophile ( $G = \text{RS}$ ,  $\text{R}_2\text{N}$ ,  $\text{O}^-$ ,  $\text{C}_2\text{H}_5$ , etc.). We will call VI  $\sigma$ - $\pi$  conjugation (as a general term for hyperconjugation) and VII internal nucleophilic displacement. (The latter term has been considered synonymous with neighboring group participation.<sup>12b</sup>) The term "anchimeric assistance" might be applied to both extremes and to all intermediate cases (VIII). Neighbor-

ing aliphatic carbon is considered to use a bonding orbital to form VIII.

The  $\sigma$ - $\pi$  conjugation by the G-C $\beta$  bond is seen by C $\alpha$  as a simple  $\pi$ -resonance effect (see ref 15c), and will be expected to correlate quantitatively with other  $\pi$ -delocalization effects. In contrast, in the extreme VII, the  $\alpha$ -carbon sees the participation of G as an SN2 process, and this process should not correlate with  $\pi$  delocalization. Furthermore, internal nucleophilic substitution will be expected to compete with rather than accelerate external nucleophilic attack.

Based on these considerations we have used four experimental methods which might differentiate between cases where the driving force is almost exclusively VI and those where it is VII: (1) substitution of resonance-stabilizing groups such as MeO-, HO-, ArO-, for R' in VI-VIII; such substitution has been shown essentially to destroy<sup>30a</sup> neighboring group participation<sup>29</sup> but should only reduce somewhat any resonance stabilization afforded by R $_2$ C(G) (this follows from the fact that SN1 reactions are accelerated much more by resonance stabilization than are SN2 reactions and the consideration that neighboring groups perform an internal SN2 reaction); (2) insertion of an aromatic group between the  $\alpha$  and  $\beta$  carbons; whereas conjugation effects are transmitted through a *p*-phenylene group, neighboring nucleophilic participation is apparently not so transmitted (eq 4); (3) correlation of solvolysis rates with carbonyl stretching frequencies; this effective correlation for aryl substituents (Figure 1) fails when neighboring group participation is involved in the solvolysis;<sup>30a,b</sup> (4) substitution of very good  $\pi$ -donating substituents at the  $\alpha$ -carbon; this accelerates both SN1 and SN2 processes, and such accelerations of SN1 reactions correlate with those of SN2 reactions<sup>15c</sup> whereas, by contrast, neighboring groups such as EtS, Cl, Br, and AcNH do not accelerate SN2 reactions.<sup>15a</sup>

**Application of These Criteria to the Effect of the Ferrocenyl Group.** In relating the behavior of the iron electrons in ferrocene (bonding and nonbonding) to the behavior of the electrons on the common neighboring groups EtS, R $_2$ C, AcNH, Br, I, etc., it must be remembered that the iron electrons which are involved are probably those in the 3d orbitals whereas in most neighboring groups 2s, 2p or 3s, 3p electrons are used. This could account for some of the differences we observe.<sup>31</sup> However, neighboring iodine behaves like RS-<sup>15</sup> with respect to the criteria mentioned, and yet iodine uses much more diffuse orbitals. In the absence of evidence to the contrary we prefer to consider nucleophilic participation by d electrons to be similar to that by s and p electrons.

**$\sigma^+$  Correlations.** We propose that  $\sigma$ - $\pi$  conjugating systems will show the same kind of response to  $\pi$ -electron demand as do other resonance-stabilizing groups. Therefore exclusive  $\sigma$ - $\pi$  conjugation requires that any quantitative correlation which holds for conjugating aromatic groups (anisyl, thienyl, etc.) will include the ferrocenyl group. The  $\sigma^+$  parameter is commonly used in such correlations, and a test of the purely resonance character of the substituent is the accuracy with which a variety of reactions correlates with the  $\sigma^+$  value.

(31) Suggested by a referee.

We have used the carbonyl stretching frequency eq 5 to calculate  $\sigma^+_{\alpha\text{-Fer}}$ ,  $\sigma^+_{m\text{-Fer}}$ , and  $\sigma^+_{p\text{-Fer}}$  and compared them with those determined by other methods in Table IV.<sup>32</sup>

Table IV.  $\sigma^+$  Values

$\sigma^+$			Method
$\alpha\text{-Fer}$	$m\text{-Fer}$	$p\text{-Fer}$	
-1.3	-0.09	-0.6	Carbonyl frequency <i>vs.</i> ArCOCH $_3$
-1.4 <sup>a</sup>	0	-0.7	Solvolysis of RCHClCH $_3$ <i>vs.</i> ArCHClCH $_3$
-1.3 <sup>b</sup>	...	...	Basicity of RCOCH $_3$ <i>vs.</i> ArCOCH $_3$

<sup>a</sup> From Figure 1. <sup>b</sup> Reference 33.

Whereas neighboring nucleophilic participation in solvolysis might account for the extreme reactivity of FerCHClCH $_3$ , which leads to our value for  $\sigma^+_{\alpha\text{-Fer}} = -1.4$ , no such phenomenon has been observed to affect carbonyl basicities or stretching frequencies. Since these three values of  $\sigma^+_{\alpha\text{-Fer}}$  are so close, it is attractive to attribute all three phenomena (including solvolysis) to  $\sigma$ - $\pi$  conjugation. This correlation is demonstrated in the plot of log *k* (solvolysis) *vs.* carbonyl stretching frequency shown in Figure 2.

**Effect of Resonance-Stabilizing  $\alpha$  Groups on  $\alpha$ -Ferrocenyl Group Acceleration.** The correlation of basicities of aromatic aldehydes with ferrocenecarboxaldehyde (eq 12) yields  $\sigma^+_{\alpha\text{-Fer}} = 1.30$ .<sup>32</sup> In solvolysis of RCHClCH $_3$  (R = aryl, ferrocenyl), we have shown  $\sigma^+_{\alpha\text{-Fer}}$  to be -1.4, in remarkably close agreement (see Table IV).

Since substitution of a methoxy group on a carbonium ion completely removes the participation by neighboring carbon,<sup>30a</sup> clearly, if there is participation by iron, it is not like that by neighboring carbon.

(32) A. N. Nesmeyanov, E. G. Perevalova, S. P. Gubin, K. I. Grandberg, and A. G. Kozlovsky, *Tetrahedron Letters*, 2381 (1966), have calculated  $\sigma^+_{\alpha\text{-Fer}} = -1.09$  from rates of protonolysis of R $_2$ Hg. Because this reaction does not follow  $\sigma^+$  we feel that the number is less reliable than our value of -1.35. We find the ratio  $\sigma_p^+/\sigma_{\alpha}^+$  to be 2.1 for either MeO or Fer, while they use the value 1.55 determined from  $\sigma_{\alpha}/\sigma_p$  rather than from  $\sigma_{\alpha}^+/\sigma_p^+$ .

(33) E. M. Arnett and R. D. Bushick, *J. Org. Chem.*, **27**, 111 (1962).

mission of Resonance Effects through a Phenyl-group. The basis of the  $\rho\sigma^+$  treatment is the mission of resonance effects through a phenylene.<sup>14</sup> Furthermore, a phenylene transmission coefficient,  $\tau$ , independent of substituent, may be defined.<sup>24</sup>

$$\log k/k_0 = \tau(\rho\sigma^+) \quad (14)$$

implies that the free-energy difference introduced in the transition state by  $\alpha$  substitution should be proportional to that caused by *para* substitution of the substituent if steric effects are small.

$$\Delta\Delta F^\ddagger_{(\alpha-\text{MeO})} = \tau\Delta\Delta F^\ddagger_{(p-\text{MeO})} \quad (15)$$

ferrocenyl (or any other) group stabilizes only by conjugation the same relationship should hold.

$$\Delta\Delta F^\ddagger_{(\alpha-\text{Fer})} = \tau\Delta\Delta F^\ddagger_{(p-\text{Fer})}$$

$$\log k_{\alpha-\text{Fer}}/k_{\alpha-\text{MeO}} = \tau \log k_{p-\text{Fer}}/k_{p-\text{MeO}}$$

If  $k_{\alpha-\text{Fer}} = k_{\alpha-\text{MeO}}$  then  $k_{p-\text{Fer}} = k_{p-\text{MeO}}$ . This is the reason we chose to compare the ferrocenyl group with the ethoxyl group.<sup>25</sup>

On the other hand, transmission of a neighboring group effect through a phenylene group destroys the relationship.

as we have shown, does not occur. If the ferrocenyl group is acting as a neighboring nucleophile, it should be without effect in the *para* position. If it is conjugative in both ways, then it should lose (relative to *p*-ethoxyl) a fraction,  $1/\tau$ , of the free energy contributed by neighboring group participation when insulated by a methyl group. Because we are discussing  $\Delta\Delta F^\ddagger$  values of about 18 kcal and  $\tau \cong 2$ , this test is a sensitive one.

The relevant rate data are shown in Table V. This table shows first that the  $\text{EtSCH}_2-$  group, which is an excellent neighboring group, has little effect in the *para* position. Secondly, although the data for the  $\alpha$ - and  $\alpha$ -Fer are rather inaccurate, it is clear that in a factor of two)

$$\frac{k_{\alpha-\text{FerCHClCH}_3}}{k_{\alpha-\text{MeOCHClCH}_3}} = \frac{k_{p-\text{FerC}_6\text{H}_4\text{CHClCH}_3}}{k_{p-\text{MeOC}_6\text{H}_4\text{CHClCH}_3}}$$

In addition to these solvolysis data, the carbonyl stretching frequencies for  $\alpha$ - and *p*-ferrocenyl ketones are almost identical transmission coefficients for a phenylene.

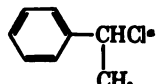

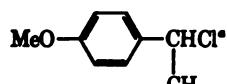

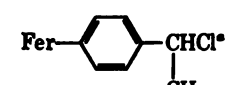

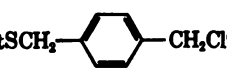

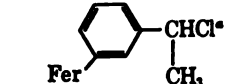

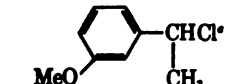

$$\left(\frac{\sigma^+_{\alpha-\text{Fer}}}{\sigma^+_{p-\text{Fer}}}\right)_{\text{CO stretch}} = \frac{1.3}{0.6} = 2.1$$

$$\left(\frac{\sigma^+_{\alpha-\text{Fer}}}{\sigma^+_{p-\text{Fer}}}\right)_{\text{solvolysis}} = \frac{1.4}{0.7} = 2.0$$

Therefore, this criterion also indicates that neighboring group participation makes a negligible contribution.

J. E. Leffer and E. Grunwald, "Rates and Equilibria of Organic Reactions," John Wiley and Sons, Inc., New York, N. Y., 1963. A better choice would have been the *p*-aminophenyl group except for synthetic and analytic difficulties (see ref 16).

tion to the stabilization of  $\alpha$ -ferrocenyl carbonium ions. The neighboring iron has little in common with other neighboring groups.

**Correlation of SN1 with SN2 Reactions on Ferrocenylmethyl Chloride.** We have recently reported<sup>20b</sup> that ferrocenylmethyl chloride is about eight times more reactive than methoxymethyl chloride toward either SN1 ethanolysis or bimolecular reaction with ethoxide ion. Since ferrocenylmethyl chloride competes with methoxymethyl chloride as well in SN2 as in SN1 reactions and neighboring group participation does not accelerate SN2 reactions, we concluded that no such acceleration was indicated in the SN1 reaction of ferrocenylmethyl chloride.

**Mechanism of Solvolysis.** Having presented experimental evidence against neighboring nucleophilic participation, we must account for rate acceleration, *exo:endo* rate ratios in IX, and retention of configuration in some other way.

We conceive the metallocene structure to be a rather basic aromatic system, which might be expected of a somewhat complexed cyclopentadienide anion. Thus, although reaction 17 would certainly be too fast to measure reducing the negative charge by bonding to

$\text{Fe}^{2+}$  (eq 18) would make the reaction sufficiently slow

to be observable. ( $\text{Cr}^0$  may be *donating* in  $(\text{C}_5\text{H}_5)_2\text{Cr}$ .) The rate acceleration (relative to phenyl) is therefore easily explained.

The only thing which would differentiate this system (reaction 19) from other aromatic systems is the Fe-C bonding, which we conceive to be greatly weakened in the transition state by  $\sigma-\pi$  conjugation.<sup>36a,b</sup> This will

determine the stereochemistry because such conjugation is much more facile when the two groups are in a *trans* configuration.<sup>37</sup>

By microscopic reversibility, the lowest energy reaction path for the reverse process takes the same *trans* geometry and gives retention of configuration.<sup>38a</sup> Therefore this process (which might be compared to an E2 elimination if the second cyclopentadienide ring is considered as the base) gives the same stereochemistry as would nucleophilic participation by unshared electrons on iron. For the same reasons, the *exo:endo* rate ratios in the solvolyses of IX are clearly consistent with the  $\sigma-\pi$  conjugation mechanism.

Either neighboring nucleophilic attack as we describe it or "direct back-side participation of iron elec-

(36) (a) Rosenblum has formulated this stabilization similarly: ref 7a, p 133; (b) the weakening of the iron carbon bonds on formation of an  $\alpha$ -ferrocenylcarbonium ion has been suggested and documented by Nesmeyanov, *et al.* For example, the diphenylferrocenyl carbonium ions readily dissociate to 6,6-diphenylfulvenes; (c) A. N. Nesmeyanov, V. A. Sazonova, and V. N. Drozd, *Dokl. Akad. Nauk SSSR*, 154, 1393 (1964); (d) A. V. Nesmeyanov, V. A. Sazonova, V. N. Drozd, N. A. Rodionova, and G. I. Zudkova, *Izv. Akad. Nauk SSSR*, 2061 (1965).

(37) V. J. Shiner, Jr., *J. Am. Chem. Soc.*, 82, 2655 (1960).

(38) (a) In the process shown in eq 20 all the upper Fe-C bonds are conceived to be weakened in going to the ion but the Fe-C<sub>1</sub> bond should probably weaken much more than the others. We have called this process "elimination" or " $\sigma-\pi$  conjugation." The latter term is probably preferable since the iron atom is not removed from the molecule. (b) We do not mean to imply that the carbonium ion has no positive character at the  $\alpha$ -carbon. Rather the resonance hybrid XV  $\longleftrightarrow$  XVI looks more like XVI than like XV (see nmr section for structures).

trons"<sup>38b</sup> as formulated by Hill and Richards suggests that the Fe-C<sub>1</sub> distance decreases during ionization to the cation I whereas the  $\sigma-\pi$  conjugation mechanism predicts no appreciable decrease.<sup>38b</sup> A comparison of the crystal structure of the cation salt with that of the alcohol should be very informative.

**Comparison of Ferrocene Reactions with Those of Alkylmetal Compounds.** Cyclopentadienylmetal compounds other than those of transition metals react rapidly with electrophiles and show other chemical behavior typical of alkylmetal compounds.<sup>39a,b</sup>

Ferrocene and other metallocenes are much less reactive toward electrophiles than are other cyclopentadienylmetal compounds.<sup>6,40-42</sup> They are also much more stable toward homolysis than are alkyl transition metal compounds. On the other hand, rates of substitution on the ring in ferrocene are much faster than those on benzene. Typical reactions which are much faster on ferrocene than on benzene are depicted in eq 1, 22, and 23.

A popular mechanism which has been considered general for these processes is<sup>6,39c,d</sup>

(39) (a) P. L. Pauson, *Quart. Rev. (London)*, 9, 391 (1955); W. F. Little, "Survey of Progress in Chemistry," Vol. 1, A. F. Scott, Ed., Academic Press Inc., New York, N. Y., 1963; (b) p 188; (c) p 153; (d) however, see M. Rosenblum and F. W. Abbate, *J. Am. Chem. Soc.*, 88, 4178 (1966), where additional results suggest that attack on iron is not a necessary part of the mechanism of electrophilic substitution on ferrocenes.

(41) S. A. Miller, J. A. Tebbboth, and J. F. Trearnine, *J. Chem. Soc.*, 632 (1952).

(42) R. B. Woodward, M. Rosenblum, and M. C. Whiting, *J. Am. Chem. Soc.*, 74, 3458 (1952).

$E^+$  can be the external electrophiles  $Ac^+$ ,  $H^+$ ,  $Ac^+$ ,  $RN_2^+$ , or the internal electrophiles  $C^+R_3$ ,  $OH^+$ .<sup>43</sup> We offer an alternative view which proposes an individual cyclopentadienylmetal bond in a locene retains some of the characteristics which are ally associated with carbon-metal bonds.<sup>6</sup> Thus regard to a single Fe-C bond we might consider ene to be a more covalent counterpart of cyclopentadienyllithium. According to this interpretation cyclopentadienide moiety has higher electron density on metal side than on the opposite side of the ring just as ethyllithium has greater electron density on lithium side of the carbon than on the opposite (XI).

X

XI

us consider reactions 1, 22, and 23 with reference structures X and XI and the known stereochemical behavior of organometallic compounds.<sup>44</sup> Electro-attack on XI is facile and occurs with retention of configuration<sup>6,44a,b</sup> by attack on the electron-rich side shown in XII. Similarly (under conditions which

XII

XIII

SE1 reactions), attack should occur preferentially on the metal side of the cyclopentadienide moiety XIII or the compound is the  $\sigma$ -bonded lithium derivative, or the covalent sandwich, ferrocene.

(25)

like the addition of HX to vinylferrocene, as in the case of all allylmetal compounds,<sup>45</sup> should be

(26)

(27)

(28)

The well-known elimination of organometallic compounds,<sup>6</sup> e.g.

(29)

might also be expected to occur rather readily with metallocene compounds as discussed above and shown in eq 20.

**Participation in  $\beta$ -Ferrocenylethyl Tosylate Solvolysis.** The formation of cyclopropanes from  $\gamma$ -metalloalkyl halides is well known.<sup>46</sup>

(30)

(31)

If we write these reactions with the usual retention of configuration observed for carbon-metal bond cleav-

age,<sup>44</sup> it becomes clear that cyclopentadienyl compounds of this type should show the same stereochemical preference whether they are  $\sigma$  bonded or sandwich compounds (eq 32 and 33).

The intermediate formed from solvolysis of  $\beta$ -ferrocenylethyl tosylate is pictured as a structure like the phenonium ion, but it is formed by a simple SE2 attack on the cyclopentadienyl carbon. The rapid rate of solvolysis of this tosylate (500 times that of phenethyl tosylate) observed by Trifan and Bacska<sup>44</sup> is entirely

consistent with the mechanisms we propose. Indeed, we would suggest that this reaction would be much more facile if iron were replaced by, *e.g.*, magnesium, which has no d electrons because C-Mg is more ionic than C-Fe.

In all these proposed reaction mechanisms, the difference between "ionic" or  $\sigma$ -bonded RM compounds and covalent sandwich compounds is considered to be that in the latter the metal is retained by bonding to the remaining diene group whereas in the  $\sigma$ -bonded compounds the metal does not bind with dienes and is lost.<sup>38</sup>

**Nmr Spectra of Metallocenylmethyl Cations.** The chemical shifts of ring ( $H_2$ ,  $H_3$ ) and  $\alpha$  hydrogens ( $H_1$ ) in XIV<sup>47</sup> and XV<sup>3e</sup> have been interpreted by Fitzpatrick,

Watts, and Pettit<sup>47</sup> in terms of structures such as XVI and by Cais, *et al.*,<sup>3e</sup> in terms of structure XVII. While

(47) J. D. Fitzpatrick, L. Watts, and R. Pettit, *Tetrahedron Letters*, 1299 (1966).

<sup>a</sup> Chemical shift in parts per million from TMS. <sup>b</sup> Reference 3e. <sup>c</sup> Reference 48a. The data were given in cps downfield from water. We have used  $\delta_{H_2O} = 5.00$  to compute the chemical shifts in ppm. <sup>d</sup>  $\Delta\nu = (\delta_{H_1} - \delta_{H_2})60$ .

we agree that the data of Cais, *et al.*,<sup>3e</sup> may be explained by structure XVII, they do not appear to exclude XVI. In Table VI are listed the data for the  $\alpha$  protons in ions XV, and in similarly substituted olefins and carbonium ions.

Table VI shows a striking similarity between the  $\alpha$ -substituent effects on the chemical shifts of  $H_1$  in ferrocenylmethyl cations and those in olefins.<sup>48a, c</sup> It is especially striking that anisyl substitution ( $R = \text{anisyl}$ ) has no greater effect than phenyl substitution ( $R = \text{phenyl}$ ) in olefins and in the cations XV. This differs from the effects of anisyl *vs.* phenyl substitution in other carbonium ions.<sup>29</sup>

Similarly, the changes in  $\Delta\nu$  shown in Table VI and attributed by Cais, *et al.*, to changes in extent of iron participation are also explicable by formulation XV. Such  $\Delta\nu$  values have been observed for metal  $\pi$  complexes of butadiene and cyclopentadiene.<sup>48d-f</sup> Furthermore, the  $\Delta\nu$ 's within the aryl series are inconsistent with the notion of decreased iron participation with increased electron supply from R.

Therefore, we believe that either the proposal of Pettit, *et al.*, or that of Cais, *et al.*, is consistent with the nmr data now available. Neither the chemical shifts of the  $\alpha$  protons nor those of the ring protons differentiate between these proposals.

## Conclusion

The results of this study appear to be inconsistent with a mechanism of solvolysis of  $\text{FerCR}_2\text{X}$  involving the same kind of neighboring group participation usually displayed by carbon or by RS groups. While we cannot exclude some novel involvement of filled d orbitals which might be consistent with our findings, we consider a mechanism of  $\sigma$ - $\pi$  conjugation simpler and preferable at this time.

interpretation is similar to that proposed earlier<sup>1</sup> and Richards<sup>2b</sup> (delocalization into the ring) as to the major stabilization of  $\alpha$ -ferrocenyl-ium ions (*i.e.*, about 80% of the stabilization). Our interpretations differ mainly with respect to stereospecific solvolyses, the *exo:endo* rate ratios and the position of the iron atom in the carbonium ion. Thus we suggest that there is no detectable bonding between iron and C<sub>5</sub> in the carbonium ion whereas *ds*, *et al.*, and Trifan, *et al.*, postulate that such  $\pi$  is sufficient to govern stereochemistry and *exo:endo* rate ratios.<sup>4a</sup>

Experimental Section<sup>4a</sup>

Procedures followed for all preparations of substituted ferrocenes and  $\alpha$ -phenethyl alcohols are the same as those used for ferrocenyl derivatives.

**Ferrocenylacetophenone.** *p*-Aminoacetophenone (11.0 g, 0.061 mole) was dissolved in 100 ml of 25% fluoroboric acid and cooled to 0° in an ice-salt bath. An ice-cold solution of 6.3 g of sodium nitrite in water was added dropwise, keeping the temperature 5°, until a positive test was obtained with starch-iodide. The white precipitate was collected on a suction filter and washed with small amounts of water, ethanol, and ether. It ended in 50 ml of cold acetic acid-water (1:1) and added to a cooled, stirred suspension of 15 g (0.805 mole) of sodium acetate in 600 ml of acetic acid. After addition was complete, the mixture was stirred overnight at room temperature. Then 2 l. of water was added, and the mixture was filtered. The solid was washed with water and sodium carbonate solution, dissolved in ether, and dried. It yielded 10.4 g of a brick red solid on evaporation. The solid was chromatographed on neutral activity II using petroleum ether-benzene mixtures. First, 5.9 g of *p*-acetophenone odor) was eluted with petroleum ether (bp 0°). Then 5.4 g of *p*-ferrocenylacetophenone was eluted with petroleum ether-benzene, mp 173–174°, after recrystallization from cyclohexane (lit.<sup>7b</sup> mp 176–178°). No attempt was made to separate other products in any of the arylation reactions. *Anal.*  $\tau$  C<sub>18</sub>H<sub>14</sub>FeO: C, 71.07; H, 5.30. Found: C, 71.07;

product on chromatography yielded 13.8 g of ferrocene. The desired ketone (6.0 g, 31% yield) was eluted next with 1:1 benzene-petroleum ether. It formed orange-brown prisms, mp 73.5–74°, after two recrystallizations from ethanol. *Anal.* Calcd for C<sub>18</sub>H<sub>14</sub>FeO: C, 71.07; H, 5.30. Found: C, 71.39; H, 5.27.

From the blue aqueous layer there was isolated 5.4 g of a brown solid, much of it evidently ferric oxide, which on chromatography afforded 3.4 g of ferrocene and 0.4 g of *m*-ferrocenylacetophenone.

***o*-Ferrocenylacetophenone.** *o*-Aminoacetophenone (5.0 g, 0.037 mole) was diazotized and added to 10.0 g (0.0538 mole) of ferrocene in 300 ml of acetic acid. Following work-up as usual, the ether-soluble product was chromatographed. Ferrocene (3.6 g) was eluted first, followed by the ketone (2.9 g, 35% yield), which was eluted with 1:1 benzene-petroleum ether. It was recrystallized from ethanol to form brown-red prisms, mp 87–87.5°. *Anal.* Calcd for C<sub>18</sub>H<sub>14</sub>FeO: C, 71.07; H, 5.30. Found: C, 70.83; H, 5.23.

Ferrocene (1.4 g, mp 171–173°) precipitated from the aqueous layer on reduction with stannous chloride. The infrared spectrum showed no detectable impurities.

**$\alpha$ -(*p*-Ferrocenylphenyl)ethyl Alcohol.** A solution of 3.0 g (0.0097 mole) of *p*-ferrocenylacetophenone in 50 ml of isopropyl alcohol was refluxed for 4 hr with 6 g of sodium borohydride. Excess sodium borohydride was then destroyed with acetone, and a few drops of water were added. The solvent was removed by evaporation and the residual yellow solid recrystallized from cyclohexane, mp 113–114°, yield 96%. *Anal.* Calcd for C<sub>18</sub>H<sub>18</sub>FeO: C, 70.61; H, 5.92. Found: C, 70.30; H, 5.96.

**$\alpha$ -(*m*-Ferrocenylphenyl)ethyl Alcohol.** The carbinol, prepared in 85% yield, was recrystallized from ether-petroleum ether, mp 86.5–87°. *Anal.* Calcd for C<sub>18</sub>H<sub>18</sub>FeO: C, 70.61; H, 5.92. Found: C, 70.62; H, 6.05.

**$\alpha$ -(*o*-Ferrocenylphenyl)ethyl Alcohol.** The carbinol was obtained as yellow needles, mp 113.5–114.5°, following recrystallization from cyclohexane; yield of purified material 80%. *Anal.* Calcd for C<sub>18</sub>H<sub>18</sub>FeO: C, 70.61; H, 5.92. Found: C, 70.41; H, 5.95.

**$\alpha$ -(*p*-Tolyl)ethyl Alcohol.** The crude reduction product was distilled at reduced pressure. The alcohol [bp 113° (13 mm)] was obtained in 80% yield;  $n_D^{20}$  1.5205 (lit.<sup>10</sup>  $n_D^{20}$  1.5232).

**$\alpha$ -(*p*-Anisyl)ethyl Alcohol.** The yield of purified alcohol [bp 128° (15 mm), lit.<sup>10</sup> bp 109–110° (2.5 mm)] was 71%;  $n_D^{20}$  1.5335 (see Table VII for nmr readings).

**$\alpha$ -(*p*-Ferrocenylphenyl)ethyl Chloride.** Procedure A.<sup>10</sup> A solution of 0.2 g of  $\alpha$ -(*p*-ferrocenylphenyl)ethyl alcohol in 50 ml of ether was cooled to 0°. Several pieces of calcium chloride were added. The solution was purged with nitrogen, and then hydrogen chloride was passed into it for 1 hr.

Procedure B.<sup>11</sup> To the cooled ethereal solution of the carbinol was added 10 ml of concentrated hydrochloric acid. The mixture was shaken and kept at 0° for 1 hr. About 50 ml of petroleum ether was added, and the layers were separated.

The ethereal solution was dried with calcium chloride for 1 hr and filtered and the solvent removed at reduced pressure. Two portions of dry petroleum ether were added and evaporated. The residual

aqueous layer was reduced with stannous chloride to yield a brown solid. This was chromatographed in a similar manner and yielded 2.35 g of ferrocene. There were several other peaks in the column but only a trace of the desired ketone. Yield of *p*-ferrocenylacetophenone based on unrecovered ferrocene was 31%.

**Ferrocenylacetophenone.** *m*-Aminoacetophenone (11.0 g, 0.061 mole) was diazotized and the salt added to 30 g (0.161 mole) of sodium acetate in 1 l. of acetic acid. The ether-soluble portion of the

NOTE ADDED IN PROOF. After this paper was submitted M. Szwarc, *Chem. Rev.*, 1, 435 (1966) criticized our initial<sup>2</sup> proposal of delocalization. The suggestions of Cais should be compared with our own here.

Boiling points are uncorrected. Analyses were performed by Dr. Pascher, Bonn, Germany.

(50) R. Fuchs and C. A. Vander Werf, *J. Am. Chem. Soc.*, 76, 1631 (1954).

(51) Procedure of J. F. Norris, M. Watt, and R. Thomas, *ibid.*, 38, 1071 (1916).

yellow solid, mp 83–84°, was highly reactive and was used without further purification. Analysis indicated that it contained 8% of starting material. *Anal.* Calcd for  $C_{18}H_{17}ClFe$ : C, 66.59; H, 5.28; Cl, 10.92. Found: C, 67.23; H, 5.78; Cl, 10.03.

**$\alpha$ -(*m*-Ferrocenylphenyl)ethyl Chloride.** Procedure B was used and the crude product, mp 86.5–88.5°, was chromatographed on activity II basic alumina, using petroleum ether. It was eluted rapidly, mp 90–90.5°, after recrystallization from petroleum ether. *Anal.* Calcd for  $C_{18}H_{17}FeCl$ : C, 66.59; H, 5.28; Cl, 10.92. Found: C, 66.04; H, 5.29; Cl, 10.94.

**$\alpha$ -(*p*-Methylphenyl)ethyl Chloride.<sup>52</sup>**  $\alpha$ -(*p*-Methylphenyl)ethyl alcohol (2 ml) was dissolved in dry benzene and cooled in an ice bath. Then 0.9 ml of phosphorus trichloride was added cautiously. A second phase appeared within 1 min. The mixture was kept at 0° for 1.5 hr. Then solid lithium carbonate was added and the solvent almost entirely removed at reduced pressure. The residual mass was suspended in petroleum ether and chromatographed on activity II basic alumina. The chloride was eluted before the carbinol. Portions of eluate were evaporated, and the infrared spectra of the chloride thus obtained were checked for absence of hydroxyl. The rest of the chloride-containing eluate was stored as the petroleum ether solution in the freezer in order to discourage polymerization;  $n_D^{25}$  1.5242 (lit.<sup>10</sup>  $n_D^{25}$  1.5232).

**$\alpha$ -(*p*-Methoxyphenyl)ethyl Chloride.** Procedure B was used. The infrared spectrum of the product,  $n_D^{25}$  1.5370, showed no hydroxyl absorption. When a weighed portion of the chloride was added to water it liberated 99.6% of the theoretical amount of hydrochloric acid, as determined by titration with sodium hydroxide.

The nuclear magnetic resonance spectrum, taken in carbon tetrachloride solution, had a three-proton doublet centered at  $\tau$  8.26 (side-chain methyl), a three-proton sharp peak at 6.32 (methoxy), a one-proton quartet centered at 5.01 (tertiary hydrogen), and a four-proton quartet centered at 2.99 (aromatic hydrogen).

***p*-Ferrocenylstyrene.** A petroleum ether solution of  $\alpha$ -(*p*-ferrocenylphenyl)ethyl chloride was passed over a column of basic activity II alumina. Immediately a green-brown band appeared on the column. Rapid elution yielded an orange-yellow solid, mp 128–128.5°, after recrystallization from petroleum ether, in about 50% yield. (Other products were not examined.) The presence of peaks at 1623, 991, and 910  $cm^{-1}$  in the infrared spectrum of the material (carbon tetrachloride solution) was indicative of a styrene derivative. *Anal.* Calcd for  $C_{18}H_{14}Fe$ : C, 75.02; H, 5.39. Found: C, 75.19; H, 5.33.

**$\alpha$ -Chloroethyl methyl ether** was prepared by the method of Henze and Murchison.<sup>53</sup>

#### Products of Solvolysis of $\alpha$ -Ferrocenylphenylethyl Chlorides.

**A.  $\alpha$ -(*o*-Ferrocenylphenyl)ethyl Chloride.** A solution of 0.0105 g ( $3.23 \times 10^{-4}$  mole) of  $\alpha$ -(*o*-ferrocenylphenyl)ethyl chloride in 95% ethyl alcohol was purged with nitrogen for 15 min. After the solution had been immersed in a 40° bath for 3.5 hr, the solvent was removed with a rotary evaporator. The residue was chromatographed on basic activity II alumina. Petroleum ether first eluted 0.003 g of a material (3%) whose infrared spectrum was characteristic of a styrene. This was followed by 0.099 g of a yellow solid, mp 71–72°, after recrystallization from ether-petroleum ether. It showed strong absorption in the infrared at 1090  $cm^{-1}$ , and analysis confirmed its identity as ethyl  $\alpha$ -(*o*-ferrocenylphenyl)ethyl ether (92% yield). *Anal.* Calcd for  $C_{20}H_{22}FeO$ : C, 71.87; H, 6.64. Found: C, 71.96; H, 6.80. Increasing proportions of benzene then eluted 0.003 g (3%) of a yellow solid, shown by its infrared spectrum to be  $\alpha$ -(*o*-ferrocenylphenyl)ethyl alcohol.

**B.  $\alpha$ -(*m*-Ferrocenylphenyl)ethyl Chloride.** A solution of 0.100 g ( $3.08 \times 10^{-4}$  mole) of  $\alpha$ -(*m*-ferrocenylphenyl)ethyl chloride in 95% ethyl alcohol was purged with nitrogen and then held at 70° for 7 hr. The solvent was removed with a rotary evaporator and the residue, a dark orange oil, chromatographed on neutral activity II alumina. About 0.009 g of the residue, dark brown in color, was insoluble. Petroleum ether first eluted 0.005 g of a yellow solid (6%) judged to be a styrene from its infrared spectrum. The styrene was followed by 0.070 g (68%) of an orange-yellow solid, mp 59.5–60.5° after two recrystallizations from petroleum ether. On the basis of infrared spectrum and elementary analysis it was identified as ethyl  $\alpha$ -(*m*-ferrocenylphenyl)ethyl ether. *Anal.* Calcd for  $C_{20}H_{22}FeO$ : C, 71.87; H, 6.64. Found: C, 72.03; H, 6.75.

Benzene-ether solutions eluted about 0.003 g (3%) of  $\alpha$ -(*m*-ferrocenylphenyl)ethyl alcohol, which was incompletely separated from a carbonyl-containing material (ca. 0.003 g), judging from infrared spectra. Some remaining darkly colored bands were very reluctantly eluted with ethanol and acetic acid and could not be characterized further.

**C.  $\alpha$ -(*p*-Ferrocenylphenyl)ethyl Chloride.** A solution of 0.416 g of  $\alpha$ -(*p*-ferrocenylphenyl)ethyl chloride ( $1.18 \times 10^{-3}$  mole, allowing for 8% carbinol contamination) was dissolved in 100 ml of 95% ethyl alcohol that had been cooled to 0° and purged with nitrogen. After 3 hr at 0°, the solvent was removed by rotary evaporator. The dark orange oil was dissolved in petroleum ether and chromatographed on basic activity II alumina. Petroleum ether rapidly eluted 0.006 g (2%) of a yellow solid, shown by comparison of infrared spectra to be *p*-ferrocenylstyrene. The styrene was followed by 0.273 g (69%) of an orange oil which crystallized after vacuum drying, mp 47.5–48.5° after recrystallization from ethyl alcohol. On the basis of infrared and nmr spectra and elementary analysis it was identified as ethyl  $\alpha$ -(*p*-ferrocenylphenyl)ethyl ether. *Anal.* Calcd for  $C_{20}H_{22}FeO$ : C, 71.87; H, 6.64. Found: C, 72.00; H, 6.61.

The nmr spectrum in deuteriochloroform had a triplet centered at  $\tau$  8.85 and a quartet centered at 6.69 (ethoxy), a doublet centered at 8.63 (methyl  $\beta$  to aromatic ring), a singlet at 6.03 (unsubstituted ferrocene ring), a sextet centered at 4.65 (substituted ferrocene ring), and a quartet centered at 2.76 (aromatic ring). The tertiary hydrogen was not resolved from the sextet at 5.65.

The ether was followed by 0.029 g (8% by weight) of a yellow solid which was eluted very slowly by petroleum ether and had mp 190–210°. It was poorly soluble in ordinary solvents, and a portion which was recrystallized from cyclohexane melted from 195 to 210°. Nearly the same melting range (195–205°) was shown by a portion which was recrystallized from ethanol. The infrared spectrum showed no bands that could not arise from a ferrocene nucleus with a hydrocarbon side chain. Lack of material and insolubility prevented obtaining a good nmr spectrum, the only clear peak being that at ca.  $\tau$  6, characteristic of unsubstituted ferrocene rings. *Anal.* (relative to those for 2,3-di-*p*-ferrocenylphenylbutane): Calcd for  $C_{28}H_{24}Fe_2$ : C, 74.76; H, 5.93; mol wt, 576. Found: C, 75.62; H, 8.02; mol wt, 611 (melting point depression).

Small percentages of benzene in the eluate brought off 0.017 g of an orange-red oil, the infrared spectrum of which had a carbonyl peak at ca. 1690  $cm^{-1}$ . Its infrared spectrum consisted of the peaks characteristic of *p*-ferrocenylacetophenone, but there were others as well, in particular, one at 1090  $cm^{-1}$  (strong), possibly an ether. Attempts to rechromatograph this fraction were unsuccessful because decomposition occurred after prolonged contact with the adsorbent.

Benzene-petroleum ether (1:3) eluted 0.049 g (4.5% allowing for that initially present) of  $\alpha$ -(*p*-ferrocenylphenyl)ethyl alcohol, characterized by melting point and infrared spectrum. The small amount of material remaining on the column, eluted with mixtures ranging to 100% ether, could not be identified. The infrared spectra were complex, and prominent in all was a strong peak at ca. 1680  $cm^{-1}$ . The "9–10 bands" characteristic of unsubstituted ferrocene rings were also evident.

**Kinetic Measurements.** The solvents were made up by volume at room temperature, using redistilled water, USP absolute alcohol, ethanol which had been refluxed and distilled over calcium hydride (for ethanol-ether mixtures), and sodium-dried reagent ethyl ether. These were saturated with nitrogen both before and after dilution. Temperature control in the range –20 to +80° was  $\pm 0.02^\circ$  or less; the very low temperatures are estimated to be accurate within  $\pm 0.3^\circ$ . Thermometers in the normal range were calibrated against an NBS thermometer, and the low temperatures were measured with a vapor pressure thermometer.

The reactions were run in conductance cells unless titration procedures were to be used. Generally, the thermally equilibrated solvent was added to the substrate in the cell. The ferrocene derivatives had to be dissolved in a small amount of ether in order to effect immediate solution. It was necessary to use quite dilute solutions (ca. 0.001 *M*) in order to avoid a falloff in rate which became pronounced after one half-life.<sup>54</sup> Insolubility of the fer-

(53) H. R. Henze and J. T. Murchison, *J. Am. Chem. Soc.*, **53**, 4077 (1931).

(54) It is unlikely that this rate change is due to internal return. We tested for ether cleavage by allowing  $\alpha$ -(*p*-tolyl) ethyl ether and 0.004 *M* HCl to stand in the solvolysis solvent for several half-lives of solvolysis and found no change in conductance. We conclude that the rate decrease results from readjustment to the product styrene.

derivatives also necessitated dilute solutions. Infinity runs were taken after at least ten half-lives. Under optimum conditions, good first-order rate plots for up to three half-lives were obtained. Conductance was shown to be proportional to hydrochloric acid concentration under the conditions employed. Five or more runs were made at each temperature, and a typical measurement follows in Table VIII.

solvolysis rate of  $\alpha$ -(*p*-methylphenyl)ethyl chloride at 55° determined by titration of liberated hydrochloric acid with sodium hydroxide. It was necessary to add an excess of 2,6-dinitrophenol to the reaction mixture, which was more than ten times as rapid as the conductance solutions, in order to avoid a drop in first-order reaction rate with time.

Solvolyses of  $\alpha$ -(*p*-methoxyphenyl)ethyl chloride at 0° and of  $\alpha$ -(*p*-methylphenyl)ethyl chloride at -70° were followed by an *in situ* titration procedure. Sodium ethoxide in the ether-ethanol kinetics was dropped in as needed in order to keep the reaction at the green end point of brom thymol blue. The titrant, added in a bulb, was forced out by mercury from a 5-mm buret. The reaction rate was controlled manually, using the valve from a titration titrator TTT1. The height of the mercury in the buret was read by a transducer, and this mercury pressure was recorded as a function of time. Thus, a continuous record of volume of ethoxide added (and of hydrochloric acid formed) could be obtained. Good linear first-order plots were obtained from these experiments, and rates compared well with those determined spectrophotometrically.

Rate parameters were calculated by the method of least squares, and these values were used to calculate rates at 25°.

**Measurement of Carbonyl Frequencies.** The ketone carbonyl frequencies were measured as 0.002–0.004 *M* solutions in carbon tetrachloride, using the double beam mode of a Cary-White Model 14 spectrophotometer. The slit width was 1.4 cm<sup>-1</sup> and the thickness 1 mm. The instrument was calibrated against water vapor peaks in the 1700-cm<sup>-1</sup> region. The mid point of the peak's maximum intensity was taken as the absorption maximum. Uncertainty in the absolute values is estimated to be about 1%. Uncertainties in relative values are smaller.

The ketones were carefully purified. The more volatile ones were purified by vpc, using a silicone column in an Aerograph A-700 "Autoprep" gas chromatograph. Acetophenone, *m*- and *p*-chloro, methyl, and methoxy derivatives were purified by this way. Amino, nitro, and phenyl derivatives were reduced to constant melting point. *p*-Acetoxyacetophenone was prepared from *p*-hydroxyacetophenone by the pyridine method. *p*-Acetamidoacetophenone was obtained by acetylation of the corresponding amino derivative, mp 173–174°, after crystallization from ethyl alcohol (lit.<sup>51</sup> mp 167°).

Anthracene, Chemicals Procurement Laboratories material, was chromatographed on neutral activity II alumina with benzene. Anthracene was eluted first, followed immediately

by 9-acetylanthracene, which was recrystallized from methanol to yield yellow prisms, mp 75–77° (lit.<sup>52</sup> mp 75–76°).

9-Acetylphenanthrene, obtained from Aldrich, was treated with Norit and recrystallized twice from methyl alcohol to yield colorless needles, mp 73–74° (lit.<sup>53</sup> mp 73–74°).

3-Acetylindole was treated with Norit and recrystallized from benzene. Colorless needles, mp 194.5°, were obtained (lit.<sup>54</sup> mp 191°).

2-Acetylfuran was treated with Norit and recrystallized from ether at 0°. It was stored in the refrigerator, since the melting point is 29°.<sup>55</sup>

1-Acetonaphthone, Eastman Kodak Technical, was separated with difficulty from 2-acetonaphthone by vapor phase chromatography, using a 5% Apiezon L on Chromosorb column (1/8 in. × 10 ft) at 180°. The collected material showed only a single peak when rechromatographed.

3,4-Methylenedioxyacetophenone, obtained from Aldrich, was treated with Norit and recrystallized from ether to yield colorless prisms, mp 86–87° (lit.<sup>51</sup> mp 88°).

2-Acetylthiophene was obtained from Matheson Coleman and Bell and its purity was checked by vapor phase chromatography on a DEGS column (0.25 in. × 10 ft) at 120°. A single peak was observed.

**Preparation and Solvolysis of *p*-Hydroxymethylbenzyl Chloride.** *p*-Xylylenediol (10 g, 0.0724 mole) was added to a mixture of 150 ml of carbon tetrachloride and 50 ml of 6 *N* HCl at 0°. The glycol dissolved, and the aqueous layer turned yellow. The mixture was stored in the freezer for 2 days and then warmed to room temperature. A carbon tetrachloride extract at that time yielded nothing, but after 1 hr much yellow oil had appeared between the two layers. The oil was removed and extracted with ether to yield white crystals, mp 55–58°, melting point unchanged after recrystallization from carbon tetrachloride. The aqueous layer had developed by then a white precipitate, which was extracted into ether; mp 53–55°.

All the crystals were combined, dissolved in chloroform, and crystallized by adding petroleum ether to the solution. In this way there was obtained 1.35 g of crystals, mp 55.5–57.5°.

A second crop, 0.49 g, was obtained in the same way, mp 56–57.5°. The second crop was sublimed at 65° (1 mm), and white crystals, mp 55–60°, were obtained. Resublimation afforded 0.224 g of material of mp 59–60°. This sample was used for analysis and kinetics. (The compound was found to be quite irritating to the skin.) *Anal.* Calcd for C<sub>8</sub>H<sub>9</sub>ClO: C, 61.35; H, 5.97; mol wt, 157. Found: C, 60.99; H, 5.63; mol wt, 174.

The chlorohydrin yielded 99% of the anticipated amount of hydrochloric acid when hydrolyzed by 50% aqueous acetone (0.1 *M* in NaOH) at 35° for 3 days.

**Kinetics.** The substrate (0.04–0.09 *M*) was dissolved in ethyl alcohol containing 0.1 *M* NaOEt at 55°. Aliquots were quenched with hydrochloric acid and back-titrated with sodium ethoxide. In both instances the reaction followed second-order kinetics. For *p*-xylene dichloride,  $k_1$  was  $6.20 \times 10^{-4}$ , and for the chlorohydrin,  $k_1 = 6.21 \times 10^{-4}$  mole<sup>-1</sup> sec<sup>-1</sup>.

**Dimerization of *p*-Ferrocenylphenethyl Carbonium Ions.** A solution of 0.406 g (0.00125 mole) of  $\alpha$ -(*p*-ferrocenylphenyl)ethyl chloride in 7 ml of chloroform was added to 10 ml of 1:1 sulfuric acid-chloroform at 0°. After 1 hr the mixture was warmed to room temperature. It stood for 3 days, after which 35 ml of water was added. The dark green aqueous layer was separated from a pale yellow organic layer. The latter yielded only a few milligrams of yellowish oil on evaporation and was not examined further. The green solution was reduced with stannous chloride and extracted with benzene to yield 0.280 g of a yellow-brown solid.

The solid was chromatographed on neutral activity II alumina with benzene-petroleum ether mixtures. An orange solid (0.065 g), mp 220–225° and only slightly soluble, was eluted with 0.5% benzene. The infrared spectrum was consistent with that of a ferrocenyl hydrocarbon although it was very weak. A petroleum

L. Shriner, R. C. Fuson, and D. Y. Curtin, "Systematic Identification of Organic Compounds," 5th ed, John Wiley and Sons, New York, N. Y., 1964: (a) p 247; (b) p 259.

ether extract of the material yielded 0.005 g, mp 188–210°. The insoluble material then melted at 225–228°. Limited solubility of the latter forced use of such a high spectral amplitude that only a qualitative nmr could be obtained (benzene). Neither chloroform, DMSO, nitromethane, nor DMF would dissolve enough of the material for a spectrum. There appeared to be the following absorptions: a doublet at  $\tau$  8.96 and 8.87; sharp peak at 6.30 (unsubstituted ferrocene ring); and two poorly resolved triplets at 6.13 and 5.73 (substituted ferrocene ring). Aromatic proton absorption could not be distinguished from that of the solvent. *Anal.* Calcd for  $C_{14}H_{14}Fe_2$ : C, 74.76; H, 5.93; Fe, 19.31; mol wt, 576. Found: C, 74.47; H, 5.89; Fe, 19.73; mol wt, 549. This represents a 17% yield of dimer, based upon amount of starting chloride.

Elution mixtures containing 5–10% benzene eluted 0.010 g of solid of mp 258–261°. *Anal.* Found: C, 69.58; H, 6.52; mol wt, 3092.

Increasing amounts of benzene eluted additional amounts of solids, which had very wide melting ranges and variable but limited solubility. These could not be recrystallized, and infrared spectra indicated little because of insolubility. Mulls were also unsatisfactory. It was assumed that these fractions were polymers of a polystyrene type.

**Preparation and Solvolysis of *p*-Chloromethylbenzyl Ethyl Sulfide (IV).** A solution of 13 ml (0.17 mole) of ethanethiol in 100 ml of absolute alcohol containing 0.40 g (0.16 g-atom) of sodium as sodium ethoxide was added to 61 g (0.34 mole) of  $\alpha, \alpha'$ -*p*-xylylene dichloride in 700 ml of *n*-butyl alcohol (precipitate). The mixture was maintained at 70–75° during the addition which required about 15 min. After an additional hour stirring at this temperature the mixture was cooled to 0° for a few hours to precipitate the excess dichloride and filtered and the solvent evaporated. The product was distilled through a short Vigreux column at reduced pressure. Four fractions were obtained at 0.4 mm. The first two cuts, bp 103–104.5°, solidified and were shown by their infrared spectra to contain starting dichloride. The third cut, 3 g, bp 104.5–106.4°,  $n_D^{25}$  1.5686, showed none of the dichloride absorption at 14.4  $\mu$  in the infrared. The fourth cut, bp 106.5–115°,  $n_D^{25}$  1.5691, also showed no dichloride. Thin layer chromatography of cuts 3 and 4 using silica gel and cyclohexane–benzene also demonstrated the

absence of dichloride, but cut 4 contained appreciable amounts and cut 3 a small amount of a second, slower moving component, presumably the disulfide. Fraction 3, which was used in kinetic runs, gave the following. *Anal.* Calcd for  $C_{10}H_{10}SCl$ : C, 59.98; H, 6.54; Cl, 17.70; S, 15.90. Found: C, 60.00; H, 6.73; Cl, 15.58; S, 18.10.

Nmr. Whereas  $\alpha, \alpha'$ -dichloro-*p*-xylene showed singlets at  $\tau$  5.56 and 2.77, fractions 3 and 4 had the spectra shown in Table IX. Solvolyses of benzyl chloride,  $\alpha, \alpha'$ -dichloro-*p*-xylene, and IV in 50 vol. % aqueous dioxane, followed as described above, gave the first-order rate constants shown in Table X.

## Substituent Effects in the Chronopotentiometric Oxidation of Ferrocene Derivatives. Internal Solvation of Certain Substituted Ferricenium Ions<sup>1</sup>

David W. Hall<sup>2</sup> and Charles D. Russell

*Contribution from the Gates and Crellin Laboratories of Chemistry, California Institute of Technology,<sup>3</sup> Pasadena, California, and the Marathon Oil Company, Denver Research Center, Littleton, Colorado. Received August 12, 1966*

**Abstract:** Chronopotentiometric quarter-wave potentials of a number of substituted ferrocenes were measured in acetonitrile solution. These new data, together with previously published data, indicate that substituent effects in this reaction are best correlated by a blending of Hammett  $\sigma_m$  and  $\sigma_p$  constants, rather than by the Hammett  $\sigma_p$  constants alone as was previously suggested. The quarter-wave potentials of acetamido- and urethano-substituted ferrocenes are anomalously low compared with those of the other compounds studied. This unusual behavior is explained in terms of direct interaction of the acetamido and urethano substituents with the positive iron atom in the oxidized species.

The degree of correlation of chronopotentiometric quarter-wave potentials of substituted ferrocenes with substituent constants such as Taft's polar con-

stants,<sup>4</sup> Brown's  $\sigma^+$  constants,<sup>5</sup> and Hammett's  $\sigma_m$

, constants<sup>8</sup> has been the subject of several investigations to date.<sup>7-9</sup>

It was concluded that these quarter-wave potentials are correlated with the Hammett  $\sigma$ , constants, and the resulting Hammett plot can then be used to obtain secondary  $\sigma$ , constants<sup>10</sup> for substituents for which such data are not tabulated. It was further concluded that the same regression line can be used to obtain the monosubstituted ferrocenes and disubstituted ferrocenes.<sup>9</sup>

In addition to the chronopotentiometric measurements in acetonitrile solution, the reduction potentials of ferrocene derivatives have been measured in ethanol solutions<sup>11</sup> and in acetic acid solution.<sup>12,13</sup>

It is the purpose of the present paper to point out the accepted view of substituent effects in the oxidation of ferrocene derivatives and, indeed, in several reactions of ferrocene compounds warrants re-evaluation.

## Experimental Section

**Measurements.** Solutions of approximately 2 mM concentration in the ferrocene compound and 0.20 *M* in reagent grade, anhydrous  $NaClO_4$  (G. F. Smith Chemical Co.) were prepared using spectral grade acetonitrile (Matheson Coleman and Bell Co.). The electrolysis cell is illustrated in Figure 1 and the reference electrode in Figure 2. The current source was a Wenking potentiostat (Elektronische Werkstätten, Göttingen, Germany) which controlled the voltage across a standard resistor in series with the cell and hence the current through the cell. Chronopotentiograms were recorded on a Moseley X-Y time recorder connected to the anode and to the reference electrode through two follower amplifiers of the DeFord type<sup>14</sup> constructed with George A. Philbrick Co. plug-in amplifiers. The ohmic drop between anode and reference electrode was measured using a method described by Anson<sup>15</sup> and found to be only a few millivolts; due correction was made to the measured potentials. All measurements were performed at 25.0°. The chronopotentiometric quarter-wave potentials determined in the present work are reproducible to within at least 10 mv.

The chronopotentiometric quarter-wave potential was interpreted as the formal oxidation potential for the given solution composition, after verifying reversibility of the electrode reaction by current-reversal chronopotentiometry.<sup>7,16</sup> Reversibility was verified in the case of all but two compounds studied. Neither 3-acetyl-1,1'-di(ethoxycarbonylamino)ferrocene nor 3-acetyl-1,1'-trimethyleneferrocene gave any distinct chronopotentiometric wave upon current reversal. This probably indicates rapid decomposition of the oxidation product. Data for these compounds are excluded from the subsequent discussion.<sup>17</sup>

**Preparation of Compounds.** Most of the compounds listed in Table IA have been described in a previous publication.<sup>18</sup>

(17) More information is available in ref 1a and b concerning chronopotentiometric studies on the two compounds mentioned above, as well as on reversibly oxidized ferrocene compounds not deemed pertinent to the present paper.

(18) D. W. Hall and J. H. Richards, *J. Org. Chem.*, **28**, 1549 (1963).

Samples used in the present study were of known analytical purity except for the compounds discussed below. These compounds were prepared according to published procedures and carefully purified. A check on sample purity was made by comparing melting points with the corresponding literature values when these were available, and by inspection of the infrared spectra.

1,1'-Di(methoxycarbonylamino)ferrocene<sup>19</sup> was prepared in a manner analogous to Rosenblum's<sup>20</sup> preparation of 1,1'-di(ethoxycarbonylamino)ferrocene. The compound was purified by chromatography on alumina followed by recrystallization from petroleum ether (melting point, sealed tube, 152–153°; no melting point cited in ref 19). The infrared spectrum of this material compared favorably with the spectrum of a sample of analytically pure 1,1'-di(ethoxycarbonylamino)ferrocene.

Methoxyferrocene was prepared according to the procedure of Nesmeyanov<sup>21</sup> and purified by vacuum sublimation. The resulting yellow needles possessed a fairly wide melting range (35–40°; sealed tube), but the upper end of the range was comparable to the reported melting point (39.5–40.5°). The infrared spectrum was in accord with the structure. The chronopotentiometric curves for this material displayed no evidence for the presence of other than a single oxidizable component.

3-Acetyl-1,1'-dimethylferrocene was donated by Hill.<sup>22</sup> The purity of the sample was rechecked since it had stood on the shelf for some time. The melting point was unchanged from the value reported originally. The infrared spectrum was in accord with the structure.

1,1'-Dibromoferrocene was prepared according to the procedure of Nesmeyanov<sup>21</sup> and purified by chromatography on alumina. Recrystallization from petroleum ether gave finely divided yellow crystals (mp 50–52°, sealed tube; lit.<sup>21</sup> mp 50–51°).

## Results

Chronopotentiometric quarter-wave potentials *vs.* the silver–silver perchlorate electrode for reversibly oxidized ferrocene derivatives determined in the present study are listed in Table I, part A. We have followed the precedent set by Little, *et al.*,<sup>9</sup> and reported the data as  $\Delta E^{1/4}$  values relative to the quarter-wave potential of ferrocene. The quarter-wave potential of ferrocene *vs.* the silver–silver perchlorate electrode was found to be 0.063 volts.

Quarter-wave potentials previously reported by other workers are listed in Table I, part B. These are  $\Delta E^{1/4}$  values relative to the quarter-wave potential of ferrocene *vs.* the standard calomel electrode. These  $\Delta E^{1/4}$  data were taken directly from ref 9, and represent in some instances, as outlined in that reference, averages of  $\Delta E^{1/4}$  data determined by several research groups. It has been established<sup>9</sup> that even though the quarter-wave potential of ferrocene *vs.* the standard calomel electrode varies considerably in the studies reported in ref 7–9, it appears to have been held reproducible for a given set of determinations by each individual research group. Thus,  $\Delta E^{1/4}$  data for the same ferrocene derivatives are closely comparable throughout the several sets of studies. We chose the silver–silver perchlorate electrode only after experiencing difficulty in obtaining stable potential measurements with the aqueous calomel electrode.

We measured quarter-wave potentials for several ferrocene derivatives which had already been studied by other workers. We found a close correspondence between our  $\Delta E^{1/4}$  data and the previously published data. Complete details of these repetitive studies are to be found elsewhere.<sup>1b,c</sup> A comparison of our measurement of  $\Delta E^{1/4}$  for 1,1'-diacetylferrocene (0.488 v)

ary blending of the  $\sigma_m$  and  $\sigma_p$  constants. The constant,  $\Sigma(\sigma_m + 2\sigma_p)/3$ , is intended to represent effects intermediate in the relative inductive and resonance effects associated with  $\sigma_m$  and  $\sigma_p$  constants. Hill<sup>25</sup> has shown that effects in the solvolysis of heteroannularly substituted methylferrocenylcarbinyl acetates<sup>1b</sup> are related by the calculated constant discussed in by either  $\sigma_m$  or  $\sigma_p$ . Since it is believed that atom stabilizes the  $\alpha$ -ferrocenylcarbonium cation during solvolysis<sup>22</sup> and thereby acquires degree of positive character, it is perhaps not surprising that substituent effects in the solvolysis are parallel substituent effects in the chronopotentiometric oxidation studies discussed here. In fact, it is shown that there is an excellent linear correlation between the solvolysis rate constant data and the half-wave potentials of the appropriately substituted ferrocenes.<sup>1b</sup> This work will be discussed in a future publication.<sup>26</sup>

Table II lists the results of statistical analyses of the data which are graphically represented in Figures 3–5.<sup>27</sup> These are merely unweighted least-squares treatments of the data. The Hammett equation was used as previously discussed by Jaffé;<sup>6</sup> therefore, the significance of the statistical parameters is the same as discussed in detail by Jaffé. We have, perhaps, taken liberties from the standpoint of the statistician in that we have selectively deleted data for substituents which do not fit a given chemical classification. This was done in order to pinpoint sources of substituent effect. We believe these liberties will not lead to incorrect conclusions to be presented. But, they do make it possible inadvertently to omit discussion of statistically significant deviations not falling into our arbitrarily picked classes of substituent effects. However, we can safely say that the orders of magnitude of the deviations are far less than is the case with data not so selectively discussed.

Although it would be desirable to include in Table II the complete data for the standard deviations of the

quarter-wave potentials, this is not warranted because of limitations on space.<sup>28</sup> When it becomes necessary to support a conclusion which cannot be adequately supported by the data presented in Table II, reference will be made to Figures 3–5. Quantitative data for deviations referred to in the Hammett plots will be cited from our files.

## Discussion

Comparison of Figures 3 and 4 demonstrates that, as previous researchers have stated, the quarter-wave potentials are better correlated with Hammett's  $\sigma_p$  constants than with the  $\sigma_m$  constants. Discussion of those data which deviate even from the  $\Delta E^{1/4}$  vs  $\Sigma \sigma_p$  plot will be deferred for the moment.

It is of interest to examine the data given in Figures 3 and 4 in more detail.

Combination of all the previously published data, with but the exception of that for iodoferrocene, and a judicious selection of our data (exclude substituents which can stabilize a positive site by strong conjugation effects) lead to a large set of data which can be correlated very well by the standards listed by Jaffé<sup>6</sup> with either  $\Sigma \sigma_m$  or  $\Sigma \sigma_p$ . Compare computation numbers 2 and 5 in Table II. For a set of 20 ferrocene deriva-

<sup>a</sup> See discussion of statistical treatment of Hammett equation in ref 6. <sup>b</sup> Refers to the standard deviation of the quarter-wave potentials from the regression line.

tives, covering a magnitude of 1.5  $\sigma$  units in the  $\Sigma\sigma_p$  plot and 1.1 units in the  $\Sigma\sigma_m$  plot, there is no difference in the degree of correlation with  $\Sigma\sigma_m$  or  $\Sigma\sigma_p$ . In fact, both correlations are excellent according to standards suggested by Jaffé. The correlation parameters are identical for both computations ( $r = 0.995$ ;  $s = 0.022$ ; and the standard deviation of  $\Delta E^{1/4}$  from the regression line is 0.021 v). Of course, in one sense the comparison here also reflects inherent weaknesses of the statistical parameters  $r$  and  $s$  as a test of goodness of fit. For this reason, visual inspection of the Hammett plots, even with all the known weaknesses of subjective influences of judgment, can sometimes be more rewarding. The same goal is achieved by utilizing the statistical data on standard deviation of quarter-wave potentials from the regression line. Arbitrarily selecting twice the standard deviation as a criterion for rejection, we find only the data point for 1,1'-di(trimethylsilyl)ferrocene anomalous in the  $\Sigma\sigma_m$  plot described by computation 2 (0.055 v compared with 0.042-v limit). Since the same  $\Delta E^{1/4}$  is reported for 1,1'-di(trimethylsilyl)ferrocene as for trimethylsilylferrocene, this anomalous point may be due to an error in the determination (or tabulation) of the quarter-wave potential. None of the 20 data points was anomalous in the  $\Sigma\sigma_p$  plot described by computation 5 according to our arbitrary criterion. Thus, unless one wishes to weigh very heavily rejection of a dubious data point in computation 2, one must conclude that the correlations with either  $\Sigma\sigma_m$  or  $\Sigma\sigma_p$ , discussed above are equally good. When the data point for iodoferrocene<sup>9</sup> (halogen substituents are among those "key" substituents one should select for an investigation of the type discussed here) is included in the comparison, then one indeed finds a better correlation with  $\sigma_p$  than with  $\sigma_m$  by visual inspection of the Hammett plots or by consideration of the standard deviations of quarter-wave potentials from the regression line. The deviation from the regression line is graphically estimated to be 0.084 v. However, if one considers only the  $r$  and  $s$  parameters of Jaffé's statistical treatment, one finds the deviation by iodoferrocene in the  $\Sigma\sigma_m$  plot is masked, and the correlations still appear to be about equally good. Thus, one would be forced to choose the  $\Sigma\sigma_p$  correlation over the  $\Sigma\sigma_m$  correlation on the basis of a single previously reported data point.

The problem of comparable correlations of data from a variety of reactions of ferrocene derivatives with either  $\sigma_m$  or  $\sigma_p$  has been a persistent one in our investigations.<sup>1b</sup>

For example, we found the ionization constants of heteroannularly substituted ferrocenoic acids (litera-

ture values were used) were only slightly better correlated with  $\sigma_p$  than with  $\sigma_m$ . Both correlations were at least "good" by Jaffé's standards.<sup>6</sup> However, these studies suffered from the fact that too few data were available (4 or 5 data points), key substituents were not included, and the  $\rho$  for the reaction was very small, thus making a choice between  $\sigma_m$  and  $\sigma_p$  more difficult for reasons cited by Jaffé.<sup>6</sup> We found that Nesmeyanov's<sup>29</sup>  $pK_a$  data for the ferrocenoic acids could be correlated just as well with the quarter-wave potentials of the appropriately substituted ferrocenes as with the Hammett constants.<sup>1b</sup> What this means is that a sufficiently extensive test of substituent effects has not yet been made for this particular reaction.

The rates of esterification of substituted ferrocenoic acids with diphenyldiazomethane<sup>30</sup> have been claimed<sup>9</sup> to be better correlated with  $\sigma_p$  than with  $\sigma_m$ . However, comparisons were made on the basis of only four data points. In our treatment of the published data, we found no justification for selecting the  $\sigma_p$  correlation over the  $\sigma_m$  correlation. A more extensive study needs to be made before this problem can be resolved. We found the published esterification rate data could be correlated equally well with the appropriate quarter-wave potentials.<sup>1b</sup> We attach no significance to that observation at the present time.

We believe the problem of equally good correlations of reaction data for ferrocene derivatives with  $\sigma_m$  or  $\sigma_p$  can best be avoided by including larger numbers of compounds in the studies than have generally been used in the past. Substituents should also be more diverse, rather than including only alkyl or carbonyl functions closely related in electronic effects. A study which includes, for example, three or four alkyl derivatives and acetyl, ester, and carboxylic acid derivatives in reality amounts to a study employing only two carefully determined data points.

Returning to the comparison of Figures 3 and 4, we find that  $\Sigma\sigma_p$  does correlate more data points than does  $\Sigma\sigma_m$  when data for substituents which are electron donating *via* a resonance interaction are considered. Thus, of the 12 compounds not used in computing the regression lines for Figures 3 and 4, six may be included in the  $\Sigma\sigma_p$  plot (computation 4 in Table II) without appreciably decreasing the excellent correlation found in the case of the 20 compounds selected for computing the regression line for Figure 4. At least

(29) (a) A. N. Nesmeyanov and O. A. Reutov, *Dokl. Akad. Nauk SSSR*, 115, 518 (1957); (b) A. N. Nesmeyanov and O. A. Reutov, *Izv. Akad. Nauk SSSR*, 926 (1959).

(30) W. F. Little and R. E. Eissenthal, *J. Am. Chem. Soc.*, 83, 4936 (1961). Table II of this reference inadvertently cites Nesmeyanov's value for the  $pK_a$  of ferrocenecarboxylic acid (6.11).

f these six compounds deviate badly in the  $\Sigma\sigma_m$  correlation, while in the  $\Sigma\sigma_p$  correlation only one of the six data points (that for 1,1'-dibromoferrrocene) deviates by more than two times the standard deviation for the entire group. If one draws the new regression line derived from computation 4 in Table II, by adding to the original 20 data points those for 1-oxylferrrocene, 2-acetyl-1-acetamidoferrrocene, and halogen-substituted ferrrocenes, a decisive trend in the data is noted.<sup>31</sup> Data points for those substituents which can donate electrons by a resonance interaction tend to fall consistently on one side of the regression line (except for the alkyl substituents) whereas points for substituents which cannot stabilize the positively charged site in this manner fall on the other side of the line. Thus, the data points for both methoxyferrrocene and 1,1'-dibromoferrrocene fall off the line in the same direction and, as pointed out above, the data point for 1,1'-dibromoferrrocene is rejected from the correlation according to our arbitrary limit.

We believe this trend indicates that  $\sigma_p$  overestimates the importance of resonance effects in the chronopotentiometric oxidation of ferrrocene derivatives. Therefore we have plotted the data vs. the constant intercept between  $\sigma_m$  and  $\sigma_p$  which Hill found to give the best correlation for rate data obtained for the solutions of methylferrrocenylcarbonyl acetates.<sup>32</sup> Computation 6 in Table II shows that the correlation for the six data points in question is somewhat improved as compared with the  $\Sigma\sigma_p$  correlation. Figure 5 graphically displays the treatment, in which  $\Delta E^{1/4}$  is plotted against  $\Sigma(\sigma_m + 2\sigma_p)/3$ .

Only one compound among the 26 used in computation 6 deviates from the regression line shown in Figure 5 by more than two times the standard deviation (namely, 1,1'-di(trimethylsilyl)ferrrocene (0.040 v compared with the arbitrary limit of 0.034 v). It certainly seems that  $\Delta E^{1/4}$  for this compound should be redefined. The data point for 1,1'-dibromoferrrocene falls almost precisely on the regression line.

We include the correlation of  $\Delta E^{1/4}$  with  $\Sigma(\sigma_m + 2\sigma_p)/3$  only to point out more strongly that  $\sigma_p$  somewhat overestimates resonance effects in the oxidation of ferrrocene derivatives. Since there is already an abundance of  $\sigma$  constants of various types mentioned in the literature, we are not recommending that our calculated constant be added to the list.

Nesmeyanov has stated that formal oxidation potentials of ferrrocene derivatives are correlated better with Taft's  $\sigma^0$  constants than with Hammett's  $\sigma_p$  constants.<sup>33</sup> The  $\sigma^0$  constants place less weight on resonance interactions between the substituents and the reaction center.<sup>33</sup> Therefore, a correlation of these constants implies a decreased resonance effect, just as does correlation with our calculated constant  $\Sigma(\sigma_m + 2\sigma_p)/3$ .<sup>34</sup>

We chose not to draw this regression line on Figure 4 since the line would become overly detailed. One may visualize this second regression line remaining about the same as the line drawn in Figure 4 in the case of points 16 and 17, but at the other end being shifted upward to pass through points 12 and 13.

A. N. Nesmeyanov and E. G. Perevalova, *Ann. N. Y. Acad. Sci.*, **137**, 103 (1965).

R. W. Taft, Jr., *J. Phys. Chem.*, **64**, 1805 (1960).

We are indebted to a referee for pointing out ref 32. Although we have not done a statistical treatment on the correlation of  $\Delta E^{1/4}$  with  $\sigma^0$ , a physical examination shows the correlation to be at least as good as that obtained using  $\sigma_p$ .

The most important discovery in the present work is that quarter-wave potentials for several of the compounds listed in Table I deviate uniformly and markedly from the regression lines shown in either Figures 4 or 5. Thus, 1,1'-di(ethoxycarbonylamino)ferrrocene, 1,1'-di(methoxycarbonylamino)ferrrocene, methoxycarbonylamino-ferrrocene, acetamidoferrrocene, 1'-acetyl-1-methoxycarbonylamino-ferrrocene, and 1'-acetyl-1-acetamidoferrrocene all are much more readily oxidized than would have been expected on the basis of the  $\sigma_p$  constants for the acetamido and urethano groups, approximate as these may be.

Even if there were no linear correlation of quarter-wave potentials with  $\Sigma(\sigma_m + 2\sigma_p)/3$ , the fact that acetamido and urethano groups behave as more powerful electron donors than the methoxy group in the oxidation reaction would be quite unexpected. There is ample evidence based on reactions of benzene derivatives to indicate that the methoxy group should be the most potent of the three in stabilizing an electron-deficient reaction center.<sup>35</sup>

Brown<sup>36</sup> and Stock<sup>37</sup> have shown that in mercuration and bromination reactions of substituted benzenes the methoxy group is about ten times more potent an electron donor than is the acetamido group.

We believe the anomalous behavior observed for the acetamido- and urethano-substituted ferrrocenes is due to a direct interaction of the carbonyl oxygen atoms of these substituents with the positively charged iron atom in the oxidized species. This interaction may be viewed as an "internal solvation" effect.

Gubin and Perevalova, in their determination of normal oxidation potentials of monosubstituted ferrrocenes in acetic acid-perchloric acid solution, postulated a direct field effect by phenyl, carbomethoxy, carboxyl, and halogen substituents.<sup>13</sup> They stated that the methoxy, acetoxy, and alkyl groups showed no such effect.

Little, *et al.*,<sup>9</sup> found no evidence in their work to support the direct field effect postulated by Gubin and Perevalova. In fact, they questioned that the field effect could be the magnitude suggested by the Russian workers for substituents such as the halogens, carboxyl, and carboalkoxy groups and yet be minor in the case of the methoxy and acetoxy groups. Little and co-workers concluded that the correlations observed in their work indicated that a direct field effect was either small or else proportional to the Hammett  $\sigma_p$  constants for the series of substituents studied.

It should be pointed out that 2-acetamido-1-acetyl-ferrrocene (compound 9 in Table I) deviates from the regression line only in the  $\sigma_m$  correlation. It appears to behave normally in the two correlations shown in Figures 4 and 5. We have previously shown that the amide hydrogen in this compound is strongly hydrogen bonded to the carbonyl oxygen of the acetyl group.<sup>18</sup> It may be that this hydrogen bond is sufficiently strong so as to restrain the amide group from rotating to a favorable position for interacting with the positive iron atom in the oxidized species. Or, it may be that the energy required to break the hydrogen

(35) Ref 1b, pp 165-170, reviews the pertinent literature available at the time.

(36) H. C. Brown and G. Goldman, *J. Am. Chem. Soc.*, **84**, 1650 (1962).

(37) L. M. Stock and F. W. Baker, *ibid.*, **84**, 1661 (1962).

bond closely approximates that gained through rotation of the amide group and subsequent coordination with the iron atom.

Little, *et al.*, found that both acetoxyferrocene and phenoxyferrocene were not only oxidized more readily than expected, but also were irreversibly oxidized. We suggest that coordination of the acetoxy and phenoxy substituents with the positive iron atom in the oxidized species may have provided a pathway for decomposition. It would seem that more research is indicated to determine why methoxyferrocene is stable and acetoxy- and phenoxyferrocenes unstable under oxidation conditions. Apparently, the urethano- and acetamidoferrocenes do not have a similar pathway for facile decomposition when oxidized.

In conflict with the present study wherein acetamido- and urethanoferrocenes are oxidized at anomalously low quarter-wave potentials, Tirouflet and Komenda observed no unusual behavior for acetamidoferrocene in a polarographic study.<sup>11</sup> The data point for this compound fell very nearly on the correlation line in their plot of the oxidation potentials of 17 ferrocene derivatives *vs.*  $\sigma_p$ . Unless the ethanol-water solvent

used in the study of Tirouflet and Komenda minimized the effect of internal solvation by the acetamido group as compared with the effect in acetonitrile, we are at a loss to explain the conflicting results. It is our feeling that a polar hydroxylic solvent system should not completely mask an internal solvation phenomenon. This problem should be investigated further.

Tirouflet and Komenda also reported that their data did not correlate nearly as well with  $\sigma_m$  or Taft's polar constants. It is interesting to note that in their  $\sigma_p$  plot the point for aminoferrocene fell off the correlation line in the same direction that the point for methoxyferrocene did in our own study. Here again it seems that the electron-donating effect of substituents is overestimated by  $\sigma_p$ .

**Acknowledgment.** We are indebted to Professor J. H. Richards and Professor F. C. Anson for their helpful comments and for financial assistance during the course of this investigation. Army Research Office (Durham) under Grant No. DA-ARO(D)-31-124-G315 and in part from the National Science Foundation under Grant No. NSF-GT5190.

## Rates and Isotope Effects in the Proton Transfers from 2-Nitropropane to Pyridine Bases<sup>1</sup>

Edward S. Lewis and Lance H. Funderburk<sup>2</sup>

*Contribution from the Department of Chemistry, Rice University, Houston, Texas 77001. Received October 5, 1966*

**Abstract:** The reaction between pyridine bases and 2-nitropropane in the presence of iodine is uncomplicated in *t*-butyl alcohol-water mixtures. In the absence of excess iodide ion and with only a small fraction of the pyridine converted to its conjugate acid, the reversibility can be neglected, and the reaction is apparently free from solvent and lyate ion catalysis. Steric retardation from 2- and 6-alkyl groups in the pyridine is significant, and comparable in magnitude to the acceleration resulting from the increase in base strength. Isotope effects measured when using 2-nitropropane-2-*d* are large and variable, increasing not only with base strength but also with steric hindrance from a value of  $k_H/k_D = 9.8$  at 24.88° for pyridine catalysis to  $k_H/k_D = 24.2$  for 2,4,6-trimethylpyridine catalysis at the same temperature. Reasons for the unusually large isotope effects are considered; both tunneling and extensive loss of zero-point energy are invoked.

The proton transfer reaction is one of the most important reactions of chemistry, because of the prevalence of hydrogen and also because of the widespread use of hydroxylic solvents, which serve as both proton donors and acceptors. Aliphatic nitro compounds are experimentally desirable as proton donors to bases because the slow reaction is not susceptible to acid catalysis, so that the interpretation of measured rates is simplified. In previous work<sup>3</sup> aqueous ethanol was used as a solvent, and complications resulting from the side reactions with iodine were significant. In the present work *t*-butyl alcohol-water was used as a solvent to avoid this difficulty, and the extent of the reverse

reaction, the existence of which has been established,<sup>3,4</sup> was reduced by minimizing the concentrations of inorganic products, acid, and iodide ion.

### Results

The rates of reaction 1 were followed by disappearance of iodine measured spectrophotometrically in a

system containing *ca.* 0.1 *M* pyridine base, *ca.* 0.1 *M* 2-nitropropane, and *ca.* 10<sup>-4</sup> *M* iodine in a solvent consisting of six volumes of *t*-butyl alcohol made up to ten with water. 1. The time dependence of absorbance at 360  $m\mu$  for iodine, propane, and 2,4,6-trimethylpyridine in aqueous *t*-butyl

The disappearance of iodine follows a zero-course, but a plot of optical density *vs.* time is linear, because both the reagent pyridine base and product iodide ion react reversibly with iodine and the extinction coefficient, but not the kinetics. Earlier work,<sup>3</sup> excess iodide ion was used to make the extinction coefficient constant, but in this case the simplification is not worth the added complexity of interpretation introduced by extensive dilution. Figure 1 shows the absorbance plotted against time for a reaction with 2,4,6-trimethylpyridine base. The curvature results entirely from variation of extinction coefficient, and this one is extreme because it was measured at 360  $m\mu$ . Most measurements were made at 468  $m\mu$ , where this effect is less marked and is not present. This plot, obtained directly from the reading spectrophotometer, was then converted to a plot of concentration of iodine (including all its components) as a function of time using appropriate extinction coefficients. The plot so obtained from the data in Figure 1 is shown in Figure 2, and the good linearity to large extents of completion is shown. The reaction in this linear portion is thus zero order in iodine. The reversal indicated by the non-zero final concentration of iodine was neglected, since data were not available before the appearance of significant curvature.

Second-order rate constants were obtained by dividing the zero-order rate constant by the product of initial 2-nitropropane and free base concentrations. Since the rate expression has been explored in detail, no searching experiments were done to verify the results were incompatible with this rate law for the blank reaction mentioned elsewhere, for correction was made. We therefore consider the most important term in the rate expression, that in eq 2 (2NP = 2-nitropropane, Py = a pyridine

$$-d(I_2)/dt = k_2(Py)(2NP) \quad (2)$$

and the ionization of nitro compounds is presumably subject to general base catalysis, one should also be concerned about the terms  $k_2(OR^-)(2NP)$  and  $k_1(2NP)$ . Following Pearson and Williams,<sup>6</sup> we attempted to suppress the  $k_2$  term by adding some acid. Lack of important contribution of this term is indicated by an experiment in which the acid was omitted,

Figure 2. The time dependence of total iodine concentration as measured by the extinction coefficients and the absorbance shown in Figure 1.

using 2,6-dimethylpyridine as the base. No significant change in rate was noted, which suggests that the lyate ion term becomes negligible with only the amount of acid produced in the first few per cent of the reaction of the iodine, which occurred before measurements were started. The absence of the solvent term was not rigorously demonstrated, but if this term had contributed heavily, the rate would not have been proportional to the concentration of free base, and a significant rate in the absence of base would have been noted. The rate constants determined as described above are shown in Tables I and II. The tabulated

## Discussion

The results in Table I can be used to show that there is significant steric hindrance in some of these reactions. Brønsted plots of the data for both the protium and deuterium compounds are shown in Figure 3.

The Brønsted correlation is rough, but the deviations of the points for the 2,6-dimethyl-, 2,4,6-trimethyl-, and 2-*t*-butylpyridines (amounting to a factor of about 5 too slow a rate for the first two bases, and about 30 for the third) are clear and can be understood in terms of steric hindrance to proton transfer. There is no obvious deviation with any of the other 2-methyl

Figure 5. Theoretical plots of  $\log k_H$ ,  $\log k_D$ , and  $\log k_H/k_D$  vs.  $pK_a$  for a proton transfer reaction.

substituents. We shall discuss the results with the the apparently unhindered bases first.

The slopes ( $\beta$ ) of the Brønsted plots are not well defined, but that for the deuterium compound is about 0.4. A small difference in the Brønsted slope between the hydrogen compound and the deuterium is not obvious from this plot, but is more conspicuous in Figure 4, in which  $\log k_H/k_D$  is plotted against  $pK_a$  of the pyridinium ion, the bases with serious steric effects being off scale. A correlation with base strength is indicated,

\* Conditions, corrections, and errors as described in Table I except for temperature.

and most of the 8 points fall reasonably on a line with a slope of 0.04, indicating that the Brønsted  $\beta$  for unhindered cases is perhaps 10% larger for the proton transfer than for the deuteron transfer reaction. This increase in isotope effect with base strength of the attacking species has often been observed before (a few of the many examples are cited in ref 3); it is clear that it cannot continue over a wide range of base strengths, for the isotope effects would become unreasonably large. Thus, this increase of 0.04 in  $\log k_H/k_D$  per  $pK$  unit would predict  $k_H/k_D = 50$  with a hypothetical base with conjugate acid  $pK_a$  of 20. Such isotope effects are unreasonable and not in accord with either experience or any theory of isotope effects. The Brønsted relationship runs into a limitation when reactions are diffusion controlled, but for this same base with conjugate acid  $pK_a = 20$ , the rate constants  $k_D$  and  $k_H$  predicted by the Brønsted coefficients of 0.40 and 0.44, respectively, are  $k_D = 0.2$  and  $k_H = 10$  l./mole sec, which are well below the diffusion-controlled limit. In order to reconcile experience and theory with this extrapolation, it is clear that the extrapolation must give way, and the Brønsted relation for either the proton

er, the deuteron transfer, or both must fail over wide range of base strengths. It is absurd to expect a conspicuous failure of the Brønsted relationship for only one isotope; it is more reasonable to expect a deviation from the relationship in both reactions.

A reasonable form for the deviation from linearity is illustrated in Figure 5, which shows the limiting behavior of one and zero as described by Eigen.<sup>6</sup> The limiting curve is also plotted (with a magnified scale), showing a maximum in  $k_H/k_D$  at some intermediate base strength associated with a Brønsted slope well removed from either limit.

It is difficult to construct any other dependence of the isotope effect on  $pK_a$  that does not lead to a rather tortuous Brønsted plot, especially since the kinetic isotope effect can reasonably be expected to be absent in the non-controlled reverse reaction at the left-hand

side. There is no obvious analytic form to the curves of Figure 5, so that it is not necessary to assume the value of 0.500 in the neighborhood of a base giving maximum isotope effect. The observed value of  $\beta = 0.4$ , which is probably near the maximum since the isotope effects are so large, is reasonable. We would expect that the Brønsted  $\beta$  would be large for a reaction with isotope effect increasing with base strength, and small when the isotope effect decreases with base strength.

It should be noted that an imaginative reader can easily see a maximum in the isotope effect in Figure 5 if it is assumed that even the single 2 substituent exerts a steric effect which influences the isotope effect. Then one should exclude these from Figure 4, and the remaining points show a maximum in isotope effect at  $pK_a$  about 6.1. If this is real, then this is the observation of such an effect with a closely related series of bases.

It is interesting that this maximum in the isotope effect on changing  $K_a$  is a consequence only of the dependence of the isotope effect on  $K_a$ . The maximum predicted from these considerations may be compared with that predicted by Westheimer<sup>8</sup> (and in different form by Melander<sup>9</sup>) for the one-dimensional transition state with hydrogen between two heavier particles. It predicts a maximum isotope effect when the force constants to the two particles are equal, and  $k_H/k_D$  is unity when either one of these force constants is greater than the other. The maximum in the isotope effect may then be expected roughly when the transition base and product base are equal in strength; the transition state should then be about halfway to the reactants and thus the Brønsted coefficient should be about one-half. It is of interest to see to what extent the present situation fits these expectations. Since the 2-nitropropane anion is probably a stronger base than pyridine bases, the ionization reaction is endothermic. Hence, following Hammond,<sup>10</sup> the transition

state is somewhat product-like but would become more symmetric if the attacking base were stronger. This consideration of basicity would lead to the conclusion that we are on the left-hand side of the maximum in Figure 5. The observed coefficient of 0.4 is then adequately close to the predicted value. There are two complicating factors which should be considered in comparing the present results with any theory. First, the proton is attached to carbon in the reagent and to nitrogen in the product, and the reaction leads to separate charges from neutral reagents. There is thus no reason to believe that the upper curves in Figure 5 should have much symmetry. If a transition state has reached the halfway point in charge separation (the condition expected with  $\beta = 0.5$ ), it need not have attained exactly the halfway point in bond strengths, such that the isotope effect is maximized. Second, the reported Brønsted  $\beta$  is based on  $pK_a$ 's measured in water, but to use it as a measure of the extent of proton transfer in the reaction under study the  $pK_a$ 's should be measured in the same solvent as is used in the reaction.

The rates and the isotope effects with the unhindered cases then present elements of interest, especially with regard to the consequences of an isotope effect that varies with base strength, but do not present any features without precedent from earlier work. The fact that the isotope effects and rates are understood makes them of greater value as a basis for the discussion of the hindered cases, which we shall now consider.

There is no conspicuous evidence for hindrance with only a 2-methyl group. We should then limit this discussion to those bases which deviate markedly from the Brønsted plot, namely 2,6-dimethylpyridine, 2,4,6-trimethylpyridine, and 2-*t*-butylpyridine. In the last case the rate was very low, and the deuterium case was too slow to measure, so that the isotope effect is quite large, but undetermined.

The very large isotope effects with 2,6-dimethylpyridine and 2,4,6-trimethylpyridine are somewhat larger than can be accounted for even by total loss of all the zero-point energy of the C-H and C-D bonds.<sup>11</sup>

The very large isotope effect ( $k_H/k_D = 19.5$  at 25°C) has also been reported for the 2-nitropropane-2,6-dimethylpyridine reaction in water solution by Bell and Goodall.<sup>12</sup> They also report work of great pertinence to the problem of variation in isotope effect with acid and base strength.

The temperature dependence of the rate for 2,4,6-trimethylpyridine (eq 4) shows that the preexponential factor ratio  $A_H/A_D$  is significantly less than unity, so that the activation energy difference is even more difficult to reconcile with zero-point energy effects alone.

$$k_H/k_D = A_H/A_D e^{\Delta E_a/RT} = 0.15e^{3006/RT} \quad (4)$$

The large isotope effect, the large activation energy difference, and the small  $A_H/A_D$  factor all suggest, as

<sup>6</sup> Eigen, *Angew. Chem.*, **75**, 489 (1963).

<sup>7</sup> If the reverse reaction has no isotope effect ( $k_H/k_D = 1$ ), then the isotope effect for the forward reaction; more strictly, the ratio of the forward and reverse isotope effects is rigorously the equilibrium isotope effect, which is usually very close to unity. This equilibrium isotope effect is illustrated in Figure 5.

<sup>8</sup> H. Westheimer, *Chem. Rev.*, **61**, 265 (1961).

<sup>9</sup> Melander, "Isotope Effects on Reaction Rates," Ronald Press, New York, 1962.

<sup>10</sup> R. S. Hammond, *J. Am. Chem. Soc.*, **77**, 334 (1955).

<sup>11</sup> Estimates of the isotope effect attainable under these circumstances depend on the values chosen for the bond vibrational frequencies. The largest estimate in print is about 18, and a smaller maximum value of about 12 arises from a calculation based upon the admittedly inadequately resolved infrared spectra of 2-nitropropane and of 2-nitropropane-2-d.

<sup>12</sup> (12) R. P. Bell and D. M. Goodall, *Proc. Roy. Soc. (London)*, **A294**, 273 (1966). We are indebted to Mr. Bell for communicating several of these results to us in advance of publication.

discussed by Bell,<sup>13</sup> that there is a significant tunnel correction, especially to  $k_H$ . The existence of a relationship between the steric hindrance and the anomalous isotope effects is strongly indicated, and it is worth considering simple explanations of this relationship.

The simplest picture of the potential barrier to a reaction is a one-dimensional plot of potential energy vs. reaction coordinate. The activation energy required is of two sorts; the first is energy required to break bonds or stretch them beyond their equilibrium distance, and the second is that to overcome repulsions between nonbonded atoms. It is clear that steric hindrance falls in the second category. At short interatomic distances, the repulsive energy between atoms, whether bonded or not, rises very rapidly as the distance decreases, so that a potential barrier with an important steric repulsion component can be expected to be very steep in the neighborhood of the maximum. The resulting high barrier, which is difficult to surmount classically, has steep sides and is, therefore, relatively thin at the top; this situation is conducive to significant contribution of tunneling.<sup>14</sup>

It has been pointed out by Johnston<sup>15</sup> that one-dimensional barrier is inadequate to understand tunneling. It is interesting that even with a two-dimensional barrier representing a three-atom linear system there is a factor which will also enhance the fraction of tunneling in sterically hindered cases. Let us consider the familiar energy contours in the plot of  $r_{AH}$  vs.  $r_{BH}$ , and consider that there is in the unhindered case a certain fraction of tunneling direct from some point  $x$  on the reaction coordinate to another point  $y$  well below the maximum on the other side of the barrier and also on the reaction coordinate. Steric repulsion will raise the entire surface at short interatomic distances, that is, near the origin, but will have little effect when all distances are large. This has a major effect on the transition state but very little effect on the region directly between  $x$  and  $y$ , not along the reaction coordinate. Thus this tunneling will be relatively unchanged, but the rate of the classical barrier passage will be greatly reduced, and the fraction of tunneling will be increased by this steric repulsion.<sup>16</sup> These explanations, which are not entirely independent, do not allow us to be quantitative, but they do help make these very large isotope effects qualitatively understandable.

It should be noted that steric repulsions in the transition state can also increase the loss of zero-point energy. The most easy deformation in the A-H-B system to get rid of repulsions between A and B is to stretch the hydrogen bond itself, and as this is stretched, the bending vibrations will become less stiff and there will be substantial loss of bending zero-point energy, leading to an isotope effect approaching the upper limit accessible from zero-point energy effects alone. We now believe in fact that both tunnel effects and large zero-point energy effects are responsible for these very large isotope

effects from results of an independent nature to be published shortly.

No mention has been made of the role of the solvent, nor can we find any evidence of any peculiar feature associated in the solvent in this reaction. Some less precise measurements with somewhat different mixtures of *t*-butyl alcohol and water showed essentially the same large isotope effects. The discrepancy between the isotope effects measured here and those reported in aqueous ethanol solution earlier<sup>3</sup> is therefore worthy of comment. The other measured isotope effects show reasonable agreement; for instance for pyridine  $k_H/k_D$  is 10.2 in *t*-butyl alcohol and 10.7 in ethanol, whereas for 2,6-dimethylpyridine we now find that  $k_H/k_D$  is 24.1 in *t*-butyl alcohol, but only 10.1 was reported in ethanol. We now believe that the values in aqueous ethanol suffer from an experimental error and possibly an error of interpretation, both of which could reduce the isotope effect. The principal experimental error is the existence of a slow iodine-consuming reaction in the absence of nitropropane which is essentially negligible for the faster reactions but which becomes serious with the slowest reactions. It will be seen from Table I in ref 3 that the slowest reactions are those of the deuterated 2-nitropropane with pyridine and with 2,6-dimethylpyridine. Since the blank reaction is faster when pyridine is substituted (either because iodination of the solvent is catalyzed more effectively by the stronger bases or because the blank reaction is in part iodination of the pyridine side chains), this blank correction is largest for the case in question of 2,6-dimethylpyridine. Our blank corrections were made assuming that this side reaction was zero order in iodine; if the reaction is first order, the correction is too big. Thus uncertainty in this blank correction makes the value of  $k_D$  for 2,6-dimethylpyridine the least accurate of all the data reported, and the  $k_H/k_D$  value the least reliable.

A possible error of interpretation in the earlier work may arise from the assumption that the terms associated with the general base catalysis in solvent and in lyate ion are negligible. In aqueous *t*-butyl alcohol these terms are indeed negligible, but in water solution both a water term and a hydroxide ion term are reported to contribute markedly.<sup>12</sup> It is therefore possible that these terms also contribute in aqueous ethanol. Since they would very likely have smaller isotope effects, the ratio of gross rates of the hydrogen and deuterium compounds would be less. We are grateful to Mr. R. P. Bell for presenting this suggestion to us before publication of this explanation.<sup>12</sup>

The absence of lyate ion term was demonstrated for pyridine solutions by showing that the rate was insensitive to the concentration of pyridinium ions. This experiment was not tried on the more strongly basic 2,6-dimethylpyridine, where the lyate ion concentration is higher. The solvent term was believed to be small, but the evidence is incomplete. The only pertinent data are rate constants measured at two different base concentrations which might be interpreted as differing by virtue of a solvent term in the rate expression instead of a change in iodine extinction coefficients as originally assumed. The data are inadequate to separate the two effects, and the blank error mentioned above makes it unlikely that it will be possible even with more data. Nevertheless, the presence of solvent and lyate ion

(14) A referee suggests that steric hindrance may hold the extreme atoms of a model triatomic system farther apart throughout, thus effectively making the barrier thicker. We have not become convinced that the barrier thickness is this simply estimated, but we present the above argument as a plausible but by no means rigorous possible explanation of the observed experimental result.

(15) H. S. Johnston and D. Rapp, *J. Am. Chem. Soc.*, **83**, 1 (1961).

(16) This suggestion was made to us by Dr. James M. Perry, whom we thank for this idea.

with smaller isotope effects would reduce the gross effect substantially in the aqueous ethanol. We therefore are inclined to weight the new isotope more heavily than the old in aqueous ethanol and do not feel that a large isotope effect near a factor of 20 in the aqueous ethanol is necessarily excessive. The minimization of all these complications in aqueous *t*-butyl alcohol is doubtless related to the basicity and acidity of this solvent and its resistance to halogenation. It was indeed the unreliability of the lowest rates in the aqueous ethanol solution that led us to reinvestigate this reaction in aqueous *t*-butyl alcohol.

## Experimental Section

**Materials.** 2-Nitropropane and 2-nitropropane-2-*d* were prepared as before;<sup>3</sup> the protium content of the deuterated species was 1% in the 2 position, as measured by the nuclear magnetic resonance spectrum. The substituted pyridines were prepared as described before, and several new ones were commercial materials purified by distillation. Impurity by gas chromatography, which was able to resolve all the compounds available, amounted to no more than 1%. 2,4,6-Trimethylpyridine was prepared by distillation from its boron fluoride complex as described before for 2,6-dimethylpyridine<sup>3</sup> to remove unhindered tertiary butyl alcohol was a commercial material of reagent grade.

**Measurements.** The solvent was usually made by diluting 0.119 *M* aqueous perchloric acid with 30 ml of *t*-butyl alcohol.

The carefully weighed appropriate amount of pyridine (about 0.4 g) was mixed with the *t*-butyl alcohol solution as then diluted to 50 ml with water, giving a solution about 0.1 *M* in pyridine.

Reactions were started by adding a concentrated solution of 2-nitropropane to this base solution until the base reached a preselected value (about 0.48) and allowed to the thermostat temperature. 2-Nitropropane, about 0.5 g weighed, was diluted to 50 ml with the above base and

iodine solution and the resulting solution was placed in a 10-cm absorption cell placed in a recording spectrophotometer set at 468 mμ as rapidly as possible. Since temperatures in the cell compartment were slightly closer to room temperature than the thermostat, because of heat transfer in the circulating system, the temperature changes in dilution and cell filling were in part compensated and the times taken for the cell to come adequately close to the compartment temperature were in fact rather small.

In order to demonstrate absence of serious error from the conversion of absorbances to concentration, the results for 2,4,6-trimethylpyridine were repeated at 360 mμ, using 1-cm cells instead of 10 to compensate for the higher extinction coefficients. The results agreed within 2%.

Controls showed that uncertainty about the reaction temperature was not a significant source of error. Temperatures were measured with a thermistor in the cell compartment with the thermostat itself used frequently as a reference to compensate for drift. The thermostat temperature was determined with a Bureau of Standards calibrated thermometer. Absolute temperatures are probably not accurate to better than  $\pm 0.1^\circ$ , but relative temperatures are limited primarily by reading accuracy and by the precision of bore of the thermometer, leading to an error probably  $\pm 0.02^\circ$ , since the calibration was smooth.

Solutions of known concentration of the base, iodine, and iodide ion in the solvent simulating various extents of reaction were made up, to determine the relation between absorbance and concentration of iodine in all its various complexed states. The record of absorbance vs. time from the rates was then converted to a concentration vs. time plot, which was linear up to large extents of completion confirming the zero order in iodine and its complexes. There was a residual iodine absorption because of the reversibility of the reaction, but this complication was avoided by using only the linear portion of the curve. The reported second-order rate constants are the slopes of these linear plots, less a blank correction amounting in the largest case to 10% of the observed rate (measured in a solution containing everything but 2-nitropropane and not followed to complete consumption of iodine, since it is so slow) and then divided by the base and nitropropane concentrations. Blank runs with the pyridine base omitted showed negligible reaction, and the measured rates were unchanged by the omission of the small amount of perchloric acid, usually added.

## The Importance of the "α Effect" in Amine General Base Catalyzed Ionization of Nitroethane

Maurice J. Gregory<sup>1</sup> and Thomas C. Bruice<sup>2</sup>

Contribution from the Department of Chemistry, University of California at Santa Barbara, Santa Barbara, California 93106. Received December 29, 1966

**Abstract:** The conversion of nitroethane to its ion by amine general-base catalysis ( $k_{2,B}$ ) and the retrograde general-acid neutralization of the anion ( $k_{2,A}$ ) have been investigated. Both  $k_{2,B}$  and  $k_{2,A}$  are correlated by the Brønsted equations for general-acid and general-base catalysis, respectively. Though the log of the rate constants for tertiary, secondary, and primary amines lie on separate Brønsted plots of parallel slope (presumably due to differences of solvation), hydrazine, N-methylhydrazine, hydroxylamine, and methoxylamine show no positive deviations from these plots. Therefore, the so-called α effect does not appear to be operative in the breaking or making of the C-H bond of nitroethane.

The term "α effect" has been used<sup>3</sup> to describe the high reactivity of nucleophiles possessing an unpaired pair of electrons adjacent (α) to the nucleophilic

This high reactivity is generally noted as a large deviation of the log  $k_{\text{rate}}$  for a nucleophile from

Postdoctoral Fellow, University of California at Santa Barbara, Santa Barbara, Calif.

to whom inquiries concerning this paper should be directed. O. Edwards and R. G. Pearson, *J. Am. Chem. Soc.*, **84**, 16

a Brønsted plot for nucleophilic displacements by a series of like nucleophiles in aqueous solution. Therefore, the α effect amounts to a nucleophilic (kinetic) parameter not predicted by the thermodynamic affinity of nucleophile for a proton. The various rationales for this kinetic effect have recently been summarized and discussed.<sup>4</sup> They include intramolecular hydrogen

Figure 1. The linear dependence of the pseudo-first-order rate constants for the reaction of glycine with nitroethane on the concentration of glycine at five pH's.

bonding to a carbonyl or similar group,<sup>5,6</sup> intramolecular general-base catalysis,<sup>6</sup> stabilization of the transition state due to overlap of the orbitals of the  $\alpha$  lone pair of electrons,<sup>8</sup> lessened solvation of nucleophiles exhibiting the  $\alpha$  effect relative to other nucleophiles of the same series,<sup>7</sup> destabilization of the nucleophile by repulsion of the nonbonding electrons,<sup>8,9</sup> high polarizability, and stabilization of the products of reaction.

Substrates upon which this effect has been noted to operate are all valence states of carbon, peroxides, and tetrahedral phosphorus (see ref 3). The question arises as to whether the  $\alpha$  effect is of importance in nucleophilic displacement on hydrogen (*i.e.*, general-base catalysis). It has been reported<sup>10</sup> that oxime anions show an enhanced effectiveness in the dehydration of acetaldehyde hydrate. The present work is concerned with the neutralization of nitroethane with a series of aliphatic amines. This reaction has received some attention by Pearson and co-workers.<sup>11</sup>

## Experimental Section

**Apparatus.** Absorbance measurements were made on Gilford Model 2000 or 220 recording spectrophotometers. Kinetic solutions were maintained at  $30 \pm 0.1^\circ$  by circulating water at this temperature through Beckman double thermostats. pH Measurements were made with a Radiometer Model 22 pH meter with a PHA 630 scale expander, using a combined glass-calomel electrode (Radiometer G.K. 2021C). The electrode was thermostated at the temperature of the kinetic runs.

**Materials.** Nitroethane (Matheson Coleman and Bell) was distilled twice through a 9-in. Vigreux column; bp  $113^\circ$ . Concentrated ammonia solution (Baker and Adamson, CP) and ethylamine (Eastman White Label) were appropriately diluted with water. Diethylamine (Eastman) and piperidine (Matheson Coleman and Bell) were distilled from barium oxide, bp  $55$  and  $103$ – $104^\circ$ , respectively. Morpholine (Eastman) was refluxed over sodium for 24 hr and distilled under nitrogen, bp  $125$ – $126^\circ$ . Methoxylamine, glycine ethyl ester (Eastman), and hydrazine (Matheson Coleman and Bell) hydrochlorides were crystallized from ethanol-

ether mixtures. Tris(hydroxymethyl)aminomethane (Matheson Coleman and Bell), glycine (Fisher reagent), and hydroxylamine hydrochloride (Baker Analyzed Reagent) were used without further purification. Methylhydrazine hydrochloride was prepared by passing dry hydrogen chloride into an ethereal solution of the amine (Matheson Coleman and Bell). The precipitate was crystallized from ethanol-ether mixtures.

**Kinetics.** The rate of disappearance of nitroethane in various buffers was followed by measuring the variation in absorbance at  $240\text{ m}\mu$ . Stock solutions of nitroethane in peroxide-free dioxane were prepared. One drop of these solutions in 2 ml of buffer gave a solution approximately  $10^{-3}$  to  $10^{-4}\text{ M}$  in nitroethane. Freshly distilled water was used to prepare buffer solutions and serial dilutions were made with  $1.0\text{ M}$  potassium chloride solution stored under nitrogen. The reactions were carried out in  $\text{T}$  cuvettes. Absorption due to the various buffers was compensated for by using a reference cell containing only the buffer solution. The concentration of buffer was always in large excess over that of nitroethane, resulting in pseudo-first-order kinetics. Reactions were routinely followed to four half-lives or more. The pH's of solutions were determined before and after each run. Pseudo-first-order rates were obtained from the slopes of plots of  $\log(\text{OD}_\infty - \text{OD}_t)$  vs. time.

## Results<sup>12</sup>

The reaction studied is of the type

If  $[\text{B}]$  and  $[\text{BH}^+]$  are in large excess over  $[\text{A}_T]$ , this equilibrium can be treated as a unimolecular equilibrium

(2), for which the rate expression is given by<sup>13</sup>

$$-\ln ([\text{AH}]_0 - [\text{AH}]_e)/([\text{AH}] - [\text{AH}]_e) = (k_{2,B}[\text{B}] + k_{2,A}[\text{BH}^+])t \quad (3)$$

where  $[\text{AH}]_0$ ,  $[\text{AH}]$ , and  $[\text{AH}]_e$  represent concentrations of AH at  $t = 0$ , at any time  $t$ , and at equilibrium, respectively. As the measured absorbance is that of the nitroethane anion,  $(\text{OD}_\infty - \text{OD}_t)$  is proportional to  $([\text{AH}] - [\text{AH}]_e)$

$$-\ln ([\text{AH}]_0 - [\text{AH}]_e) + \ln (\text{OD}_\infty - \text{OD}_t) = (k_{2,B}[\text{B}] + k_{2,A}[\text{BH}^+])t \quad (4)$$

Thus the slope of a plot of  $\log(\text{OD}_\infty - \text{OD}_t)$  vs.  $t$  is equal to  $0.434(k_{2,B}[\text{B}] + k_{2,A}[\text{BH}^+]) = k_{\text{obs}}$ . As the neutralization is also catalyzed by hydroxide ion this term is included in  $k_{\text{obs}}$  which is then equal to  $(k_{2,B}[\text{B}] + k_{2,A}[\text{BH}^+] + k_{\text{OH}}[\text{OH}^-])$ . Thus, a plot of  $k_{\text{obs}}$  vs.  $[\text{B}_T]$  is linear, of slope  $k_2'$  and intercept  $k_{\text{OH}}[\text{OH}^-]$  (Figure 1)

$$k_2' = k_{2,B}([\text{B}]/[\text{B}_T]) + k_{2,A}([\text{BH}^+]/[\text{B}_T]) \quad (5)$$

and

$$k_2' = k_{2,B}[K_a'/(K_a' + a_H)] + k_{2,A}[a_H/(K_a' + a_H)] \quad (6)$$

A plot of  $k_2'(K_a' + a_H)$  vs.  $a_H$  is linear of slope  $k_{2,A}$  and intercept  $k_{2,B}K_a'$  (Figure 2). For amines of high

(12) Abbreviations used in this study are:  $[\text{B}_T] = [\text{B}] + [\text{BH}^+]$

where B and  $\text{BH}^+$  represent amine and its conjugate acid;  $k_{\text{obs}}$ , pseudo-first-order rate constant at constant pH and  $[\text{B}_T]$ ;  $k_2'$ , apparent second-order rate constant at a fixed pH;  $k_{2,A}$ ,  $k_{2,B}$ , pH-independent second-order rate constants for general acid and general base catalyzed reactions, respectively;  $a_H$ , hydrogen ion activity as determined by the glass electrode,  $[\text{OH}^-] = 1.48 \times 10^{-14}/a_H$ .

the acid-catalyzed rate constant is small and  $K_{\text{a}}' + a_{\text{H}}$  was a constant equal to  $k_{2,\text{B}}K_{\text{a}}'$ . Kinetic studies using methoxylamine and hydroxylamine were carried out in 0.1 M borate buffer to maintain constant pH. Rate constants for these amines were determined from the slopes of plots of  $k_{\text{obsd}}$  vs.  $[\text{B}_\text{T}]$ . In all other cases the nucleophile and its conjugate acid were used to maintain a constant pH.

Figure 2. The linear dependence of the product  $k'_2(K_{\text{a}}' + a_{\text{H}})$  on hydrogen ion activity for the reaction of glycine with nitroethane.

The rate constants for the reaction of 13 amines with nitroethane derived by these methods are given in Table I. The rate constant for hydroxide was obtained by plotting the intercepts at  $[\text{B}_\text{T}] = 0$  from buffer dilution plots vs.  $[\text{OH}^-]$ . The buffers used were ethylamine, glycine, and ammonia.

The equilibrium constants  $K_{\text{e}}$  for (1) are given by

$$K_{\text{e}} = k_{2,\text{B}}/k_{2,\text{A}} = [\text{BH}^+][\text{A}^-]/[\text{AH}][\text{B}] \quad (7)$$

where the concentration terms refer to equilibrium concentrations

$$K_{\text{e}} = [\text{A}^-]_{\text{e}}a_{\text{H}}/[\text{AH}]_{\text{e}}K_{\text{a}}' = K'_{\text{aNE}}/K_{\text{a}}' \quad (8)$$

and  $K'_{\text{aNE}}$  is the calculated dissociation constant of nitroethane. The calculated constant as obtained for each amine is given in Table I.

### Discussion

The rate constants for the general-base neutralization of nitroethane by 13 amines are given as a Brønsted plot in Figure 3. Comparison of this Brønsted plot with that of Pearson and Williams<sup>11</sup> shows that the behavior of the various classes of amines are essentially the same, the only difference being in the slope used for primary amines (0.50 vs. 0.65 for Pearson and Williams' estimate).

Figure 3. Brønsted plot for the reactions of 14 bases with nitroethane. The numbers refer to the compounds in Table I. No statistical corrections have been made.

The dissociation constants ( $K'_{\text{aNE}}$ ) for nitroethane determined from the rate constants for primary amines are in good agreement with that found by half-neutralization ( $3.6 \times 10^{-9}$  at 30°).<sup>14</sup> However, the values derived from rate constants with secondary amines differ considerably from those obtained by half-

(14) D. Turnbull and S. H. Maron, *J. Am. Chem. Soc.*, **65**, 212 (1943).

neutralization. This is believed to be due to a statistical factor, and that the true equilibrium constant should be expressed in terms of the number of equivalent protons on the conjugate acid of the amine. In order to correlate the equilibrium constants found with secondary amines (two protons) with those for primary amines and hydronium ion (three protons), the former constants were multiplied by a factor of  $2/3$ . This correction gave a value for the  $K_a'$  of nitroethane of  $4.1 \times 10^{-9}$ , which is close to the value found with primary amines ( $3.9 \times 10^{-9}$ ).

The possibility that the rates obtained were for reaction of the amine species with the tautomeric *aci*-nitro forms of nitroethane and its anion (9) was discounted, as the  $pK_a'$  obtained from the kinetic data is that for nitroethane whereas the  $pK_a'$  of *aci*-nitroethane is approximately 5. In the pH range studied (7–11) the

equilibrium concentration of *aci*-nitroethane would be so small that equilibrium 9b can be ignored.

The order of catalytic efficiency for amines in this reaction (*i.e.*, tertiary > secondary > primary) has been attributed to solvation effects by Pearson and Williams.<sup>11</sup> The same order of nucleophilicity of amines (*i.e.*, tertiary > secondary > primary) has also been noted with phosphate<sup>16</sup> and sulfate<sup>16</sup> esters and has also been attributed to solvation effects. It is interesting to note that these substrates are sensitive to the  $\alpha$  effect. However, toward phenyl acetate primary and secondary amines lie on a single Brønsted plot whereas tertiary amines exhibit a negative deviation from this plot.<sup>4</sup> A possible explanation for this apparent anomaly is found in the fact that the bond from nucleophile to substrate is little formed in the transition states for substrate equals phosphate or sulfate esters whereas when the substrate is phenyl acetate the bond is much more completely formed. This suggestion is supported by the small Brønsted  $\alpha$  constants for the former substrates (0.20 and 0.13, respectively) as compared to the large value for the latter substrate (1.05). Therefore, steric effects outweigh solvation effects for phenyl acetate while steric effects are of little importance for phosphate and sulfate esters. This contention finds support in the much greater nucleophilicity of azetidines and aziridine toward phenyl acetate as compared to acyclic secondary amines.<sup>17</sup>

The rate constants for the general base catalyzed reactions of hydrazine, hydroxylamine, and methoxylamine with nitroethane do not deviate significantly from the Brønsted plot for primary amines (Figure 3). The rate constant for methylhydrazine lies on the Brønsted plot for secondary amines, in agreement with Condon's<sup>18</sup> suggestion that protonation of alkylhydrazines occurs at the nitrogen bearing the greater number of

alkyl groups. We can therefore find no evidence for an  $\alpha$  effect for hydrazine, methylhydrazine, hydroxylamine, or methoxylamine in this reaction. The value of 0.5 for the slope of the Brønsted plot suggests that the proton has moved considerably in the transition state, and that any effect operating on the ground state of either products or reactants should be observable. This confirms that the reactivity in proton abstraction of these amines is adequately related to their  $pK_a$ 's.

General base catalyzed proton abstraction differs from nucleophilic displacement reactions on other elements on two points. Whereas the latter must involve direct attack of the nucleophile on the substrate molecule or capture of carbonium ion, etc., the former may operate through a water molecule in a manner analogous to proton transfer in water.<sup>19</sup> Regardless of the mechanism of the proton abstraction, the un-

shared pair of electrons of the base are not considered<sup>4</sup> to be greatly perturbed in the transition state, whereas considerable perturbation of these electrons occurs in other nucleophilic displacements. Thus proton abstraction and nucleophilic displacements are not strictly analogous in that proton abstraction is insensitive to polarizability of the nucleophile.

As amines which exhibit the  $\alpha$  effect are similar in polarizability (as measured by molar refractivity) to those which do not, the  $\alpha$  effect must be a kinetic parameter which is not described by the  $E_a$  or  $P$  terms of Edwards.<sup>20</sup> Our results eliminate such ground-state phenomena as diminished solvation as a cause of the  $\alpha$  effect in amines such as hydrazine since amine-catalyzed ionization of nitroethane is sensitive to solvation changes at the basic nitrogen.

The attribution of the high reactivity of oxime anions in the dehydration of aldehyde and ketone hydrates to an  $\alpha$  effect<sup>8</sup> is probably not valid, as this too could be caused by solvation differences between these anions and the carboxylate and phenolate anions used as references. This is supported by the fact that water exhibits an equally great positive deviation from the Brønsted plot. However, for the general base catalyzed hydrolysis of ethyl trifluorothiolacetate<sup>21</sup> and the self-assisted general base catalyzed aminolysis of phenyl acetate<sup>4</sup> the  $\alpha$  effect is probably of importance and for the latter process of greater kinetic significance than for simple nucleophilic attack of amine on ester. These reactions differ from the neutralization of nitroethane in that they involve an actual nucleophilic attack on an unsaturated center and in addition proton transfer from nitrogen or oxygen rather than from carbon. It is possible that work in process may provide a rationale for these observations.

# A Kinetic and Isotopic Study of the Decomposition of Monoperoxyphthalic Acid

R. E. Ball,<sup>1a</sup> J. O. Edwards,<sup>1a</sup> M. L. Haggett,<sup>1b,c</sup> and Peter Jones<sup>1b</sup>

Contribution from the Metcalf Chemical Laboratory of Brown University, Providence, Rhode Island, and the Department of Physical Chemistry of the University of Newcastle, Newcastle upon Tyne, England. Received January 10, 1967

**Abstract:** The mechanism of the decomposition of monoperoxyphthalic acid has been investigated. The rate law is analogous to those found for other monosubstituted peroxides (second order in peroxide with a maximum rate at pH equal to pK<sub>a</sub> of peroxidic proton). The isotope data are consistent with previously observed cases in that the data are explicable in terms of two competing transition states of identical composition but different configuration.

The thermal decomposition of peroxy acids in aqueous solution to form the parent acid and oxygen has been the subject of a number of recent investigations. Edwards, *et al.*,<sup>2-4</sup> have studied the kinetics of the decomposition of two aliphatic peroxy acids and the cyclic peroxy acids Caro's acid and peroxymonophosphoric acid. Goodman and Robson<sup>5,6</sup> have studied the decomposition of peroxybenzoic acid and a series of substituted peroxybenzoic acids. The latter workers have also investigated Caro's acid and have obtained results in agreement with those reported by Edwards. Independent data on peroxybenzoic acids also are in good agreement.<sup>7</sup>

In all cases it has been found that the rate of peroxy acid decomposition is second order in total peroxy acid concentration, with a maximum rate constant at a pH equal to the pK of the proton bound to the peroxide group. The results are consistent with the idea that decomposition occurs by nucleophilic attack of the peroxy acid upon the undissociated peroxy acid molecule, where there has been some question as to the electrophilic site at which this attack occurs. Whereas Edwards and Goodman and Robson advanced arguments which led them to conclude that attack was at the carbonyl carbon of the peroxy acid (II) (sulfur or phosphorus in the case of Caro's acid and peroxymonophosphoric acid, respectively). These two activated complexes can be distinguished by a tracer technique. Mechanism I

predicts that, from a mixture of doubly oxygen-18-labeled peroxy acid and unlabeled peroxy acid, some scrambled molecular oxygen (mass 34) should be obtained. Mechanism II predicts that under the same condition no scrambling should occur. Two cases have so far been investigated. In the case of peroxyacetic acid Edwards and co-workers<sup>3</sup> found a distribution of isotopic label in product oxygen corresponding to 83% of the reaction occurring *via* II. Studies of Caro's acid<sup>4</sup> yield the result that 91% of the reaction occurs *via* I. Thus it appears likely that the two mechanisms, which yield identical kinetic form and differ only in the conformation of the transition state, are operating simultaneously.

The double-labeling method has not yet been applied to the case of substituted peroxybenzoic acids, but the experiments cited above suggest that if the carbonyl carbon electrophilic site is sterically hindered, then attack at outer peroxidic oxygen (I) may be favored. Monoperoxyphthalic acid is a most suitable peroxy acid to test this idea since the pK of the peroxy acid proton is 8.2, and the pK of the carboxylic acid proton is -0.5,<sup>8</sup> so that around pH 8 decomposition would arise from attack of the dinegative ion upon the mononegative ion. Thus the electrostatic situation is similar to that with Caro's acid (attack of SO<sub>3</sub><sup>2-</sup> on HSO<sub>3</sub><sup>-</sup>) and additional steric hindrance is provided by the *o*-carboxylate group.

This paper describes the results of our investigation of the decomposition of monoperoxyphthalic acid. Studies of the hydrolysis of monoperoxyphthalic acid are reported elsewhere.<sup>8</sup>

## Experimental Section

**Monoperoxyphthalic acid** was prepared according to the method of Bohme.<sup>9</sup> The product was a mixture of peroxy acid and phthalic acid. Various preparations yielded samples containing 40-60% w/w monoperoxyphthalic acid. The preparation of doubly oxygen-18-labeled monoperoxyphthalic acid followed the same procedure except that, to the hydrogen peroxide used, was added sufficient H<sub>2</sub>O<sub>2</sub><sup>18,19</sup> to give a mole fraction of H<sub>2</sub>O<sub>2</sub><sup>18,19</sup> ≈ 0.04. H<sub>2</sub>O<sub>2</sub><sup>18,19</sup> was prepared from water containing 97 atom % O<sup>18</sup> (Yeda Research and Development Co., Ltd., Rehovoth, Israel) by the electric discharge method.<sup>10</sup>

Figure 1. Second-order rate constant for decomposition of peroxyphthalic acid as a function of pH, temperature 24.6°.

**Buffer Components.** Analar  $\text{Na}_2\text{CO}_3$ ,  $\text{NaHCO}_3$ ,  $\text{Na}_2\text{HPO}_4$ , and  $\text{KH}_2\text{PO}_4$  were used. Reagent grade phosphates were found to give an enhanced decomposition rate (about 8%) compared with Analar materials. Analar 72% perchloric acid and 1 M NaOH (diluted to suitable concentrations) were used to adjust pH where necessary. EDTA, which was added to sequester trace metal cations, was recrystallized as described by Blaedel and Knight.<sup>11</sup> Laboratory distilled water was further purified, either by using a mixed-bed ion exchanger, or by two further distillations from alkaline  $\text{KMnO}_4$  and dilute phosphoric acid, respectively. Other reagents were of Analar grade where possible.

**Procedures.** For the decomposition kinetic studies about 0.5 g of peroxyphthalic acid-phthalic acid mixture was weighed directly into a flask and the required volume of 1 M NaOH added to neutralize the phthalic acid and also the carboxylic acid proton of the peroxy acid. Buffer solution (50 ml) consisting of  $x$  ml of 0.33 M  $\text{Na}_2\text{HPO}_4$  (or 0.67 M  $\text{NaHCO}_3$ ) + (60 -  $x$ ) ml of 0.33 M  $\text{KH}_2\text{PO}_4$  (or 0.67 M  $\text{Na}_2\text{CO}_3$ ) + 0.65 ml of 0.1 M EDTA solution was added, the solid dissolved, and the solution allowed to come to thermostat temperature. Samples (5 ml) were withdrawn by pipet, quenched in 30 ml of acetate buffer (pH  $\approx$  3) containing KI, and titrated with 0.1 N sodium thiosulfate using starch indicator.

Second-order graphs of the results were linear for at least two half-lives. Deviations at longer reaction times were observed, and the experiments at pH  $\leq$  7 were less satisfactory because hydrolysis of the peroxy acid occurred. Two other buffers were tried out near pH 8. Tris buffer (pK = 8.1) was very rapidly oxidized. With  $\text{NH}_3\text{-NH}_4\text{H}_2\text{PO}_4$  buffers, the reaction became first order in peroxy acid. Botvinnik<sup>12</sup> has reported a reaction between ammonia and peroxybenzoic acid.

The apparatus and technique used in the isotopic-labeling experiments was the same as that described previously.<sup>4,5</sup>

## Results

Figure 1 shows the experimental values of the second-order rate constants for the decomposition reaction at 24.6° as a function of pH. The points lie on a curve with a maximum rate constant of  $5.6 \times 10^{-3}$  l. mole<sup>-1</sup> sec<sup>-1</sup> at pH 8.2. The proton bound to the peroxide group in peroxyphthalic acid has a pK =  $8.2 \pm 0.1$  at 25°.<sup>8</sup> Since the dissociation of the carboxylic acid proton in peroxyphthalic acid has pK  $\approx$  0.5, the decomposition reaction may be formulated, following Ball and Edwards,<sup>2</sup> as an attack of the dianion  $-\text{O}_2\text{CC}_6\text{H}_4\text{CO}_3^-$  upon the monoanion  $-\text{O}_2\text{CC}_6\text{H}_4\text{CO}_3\text{H}$ . The curve in Figure 1 was constructed using this model and the numerical values noted above. At pH  $\leq$  7, the experimental rate constants deviate appreciably

from the theoretical curve. In this region the decomposition and hydrolysis reactions<sup>4</sup> overlap so that kinetic data for the decomposition reaction alone become much less reliable.

Table I shows the results of isotopic-labeling experiments carried out at pH 8.5 and room temperature ( $\approx$  20°). The composition of the hydrogen peroxide used in the preparation of labeled peroxyphthalic acid was determined by mass spectrometric analysis of the evolved oxygen from reaction with ceric ammonium sulfate in acid solution. The values quoted are the means of four experiments. Some samples were analyzed on a Consolidated-Electronics 21-103 mass spectrometer at Harvard University; the remainder on a

Table I. Isotopic Tracer Results for Peroxyphthalic Acid Decomposition

Source of oxygen	Composition of oxygen gas, mole %		
	$\text{O}_2^{32}$	$\text{O}_2^{34}$	$\text{O}_2^{36}$
$\text{H}_2\text{O}_2$	$95.8 \pm 0.1$	$0.6 \pm 0.1$	$3.6 \pm 0.1$
Peroxyphthalic acid decomposition (pH 8.5 phosphate buffer)	$93.6 \pm 0.2$	$5.4 \pm 0.3$	$1.0 \pm 0.1$
$\text{H}_2\text{O}_2$ from hydrolysis of peroxyphthalic acid	95.2	0.8	3.9

Hitachi-Perkin-Elmer mass spectrometer. The results from the two instruments were in good agreement. As a check that scrambling did not occur during synthesis of peroxyphthalic acid, a sample of the labeled peroxy acid was hydrolyzed in phthalate buffer solution at pH 4 in the presence of  $10^{-2}$  M EDTA, and the hydrogen peroxide produced was then allowed to react with acid ceric ammonium sulfate solution. The results of the check experiment are shown in the third line of Table I. It must be concluded from the data in the second line that the amount of scrambling (indicated by per cent  $\text{O}_2^{34}$ ) is extensive but not complete, and that this scrambling occurred during the process of decomposition.

## Discussion

The kinetic data conform well to the pattern found for other peroxy acids and are described equally well by either mechanism I or II. The isotopic tracer results cannot be explained by either mechanism alone. If it is assumed that both mechanisms contribute to the total reaction, then a statistical analysis, in which it is assumed that peroxy acid species of all isotopic distributions will react with each other at a rate unaffected by isotopic mass, yields the result that  $74 \pm 4\%$  of the product oxygen molecules derive from mechanism I. Thus, in this reaction, decomposition *via* displacement on oxygen by oxygen (I) predominates over decomposition *via* attack at the alternative carbonyl carbon electrophilic center (II). This result was expected since, in peroxyphthalic acid, we have chosen a molecule in which the latter reaction path would be disfavored. It must be concluded that the decomposition of derivatives of peroxycarboxylic acids will not generally occur exclusively by attack at carbonyl carbon. Indeed the present results reinforce the idea<sup>4</sup> that peroxy acid decompositions occur by two competing pathways having identical rate laws and differing only in the conforma-

of the transition state. In no case so far investigated does either mechanism alone completely satisfy kinetic and isotopic tracer results.

The investigation of the decomposition of a series of substituted peroxybenzoic acids by Goodman, *et al.*<sup>6</sup> present the most complete study of a group of naturally closely related acids and the data suggest the contribution of decomposition by path I may be inappreciable in this series. For this series of reactions there is no simple Hammett  $\sigma\rho$  relationship between the logarithm of the rate constant and  $\sigma$  since substituents in the aromatic ring affect both substrate nucleophile instead of only the substrate and also the two mechanisms should have different  $\rho$  values. Indeed it was found<sup>6</sup> that the decomposition constants exceeded that for peroxybenzoic acid whether electron-releasing or -attracting groups were introduced in the benzene ring.

The convenience and the usefulness of the doubling method for study of peroxide decompositions exemplified well by the present investigation. Some reaction systems to which this technique is being applied

at present are the paramagnetic peroxyborates,<sup>13</sup> the tetraperoxychromate ion,<sup>14</sup> and peroxyphthalic acid.<sup>15</sup> A combined kinetic and isotope study of the decompositions of substituted peroxybenzoic acids would give data of considerable value in understanding the factors which govern the reactivities of carbonyl carbon and peroxide oxygen to peroxyanions.

## The Decomposition of Aryl Iodine Diacetates

J. E. Leffler and L. J. Story<sup>1</sup>

Contribution from the Department of Chemistry, Florida State University, Tallahassee, Florida 32306. Received December 2, 1966

**Abstract:** The decomposition of aryl iodine diacetates takes place by three mechanisms: nucleophilic displacement within an ion pair to give aryl acetate and iodine acetate (the major reaction), homolysis to aryl iodide and acetoxy radicals, and induced homolysis. The intermediate iodine acetate decomposes rapidly to carbon dioxide and methyl iodide, but may be trapped completely by cyclohexene. The radical chain homolysis of phenyl iodine diacetate is enhanced by di-*t*-butyl peroxide.

The decomposition of phenyl iodine dibenzoate<sup>2</sup> in aromatic solvents gives clear indications of the presence of phenyl radicals,<sup>3a,b,c</sup> and it was at one time generally presumed to consist entirely of homolysis to acyloxy radicals, in a process such as eq 1 or the corresponding single-step mechanism. However, a detailed study of the products and kinetics re-

vealed a reaction of considerable complexity.<sup>3a</sup> One of the products, in 8–25% yield, is phenyl benzoate. Kinetic experiments established that the phenyl moiety of that ester comes exclusively from the aryl

iodine moiety of the dibenzoate and not at all from benzyloxy-derived phenyl radicals. This suggested that at least part of the reaction goes by way of an internal nucleophilic displacement (eq 2), closely analogous to a well-established major route for the decomposition of diaryliodonium compounds.<sup>4</sup> Kinetic and other evidence indicated that the intermediate iodine benzoate interacted with additives such as benzoic anhydride or benzaldehyde to induce a radical chain decomposition of the dibenzoate, but the details of the mechanism remained conjectural. The behavior of the diacetate, as reported in the present paper, appears to be simpler and more amenable to mechanistic interpretation.

**The Ion Pair Process.** Table I and Figure 1 show the products and typical kinetic behavior of the decomposition of phenyl iodine diacetate in chlorobenzene under anhydrous conditions.<sup>5</sup> The second yield col-

(4) See, for example, F. M. Beringer and R. A. Falk, *ibid.*, 4442 (1964).

(5) Unless otherwise noted, the solvent is chlorobenzene containing 0.1 M acetic anhydride to reactylate any diacetate that may be hydrolyzed by traces of water. Within experimental error, the presence of this amount of acetic anhydride has no effect on the decomposition rate. Although the direct reaction between traces of water and acetic anhydride in chlorobenzene at 126.8° is very slow, the indirect reaction in the presence of phenyl iodine diacetate is extremely fast. Unless

yield yet capable of reacting still more rapidly with cyclohexene is undoubtedly iodine acetate. The expected diversion product, 2-iodocyclohexyl acetate, is indeed isolated, although in low yield. Reactions 2 and 3 account for 70–75% of the decomposition in the absence of cyclohexene.

water is carefully excluded or removed in this way the rates are not reproducible.

Iodine acetate has never been isolated, but has been postulated as an intermediate in the Hunsdiecker and Simonini reactions, the reaction of lead tetraacetate, iodine, and carboxylic acids,<sup>6,7</sup> the reaction of iodine and peracetic acid with cyclohexene<sup>8</sup> or with aromatic compounds,<sup>9</sup> in the decomposition of iodine triacetate,<sup>10</sup> and the decomposition of acetyl peroxide in chlorobenzene in the presence of iodine.<sup>11</sup>

Figure 2. Effect of varying cyclohexene concentration on the rate of decomposition of 0.034 *M* phenyl iodine diacetate in chlorobenzene at 126.8°: ○, 0.181 *M* cyclohexene; ●, 0.0678 *M*; □, 0.0271 *M*; ●, 0.013 *M*.

The decomposition of phenyl iodine diacetate in the presence of cyclohexene is complicated in its later stages by a secondary reaction between phenyl iodine diacetate and 2-iodocyclohexyl acetate. This reaction accelerates the decomposition of the diacetate as 2-iodocyclohexyl acetate accumulates in the latter part of each run, and increases the yield of iodobenzene and acetic acid at the expense of phenyl acetate. Experiments in which 2-iodocyclohexyl acetate was added initially gave a very fast decomposition of the phenyl iodine diacetate from the beginning of the reaction. These rates were not readily reproducible, however, and in view of the instability of 2-iodocyclohexyl acetate and the difficulty in obtaining pure samples of known stereochemical composition the reaction was not investigated further. Judging from the yield data in Table I, the accelerated part of the decomposition in the presence of cyclohexene gives iodobenzene, acetic acid, and benzene as the major products. Since

nal phenyl groups are otherwise accounted for, mole % of benzene probably comes from the ene. A direct chain transfer between acetoxy and cyclohexene to give radicals responsible induced decomposition of the phenyl iodine is unlikely in view of the slowness of the initial position. A similar chain transfer between radicals and 2-iodocyclohexyl acetate, however, at the delayed acceleration produced by added ene, the immediate acceleration produced by iodocyclohexyl acetate, and also the formation of ene and acetic acid. We envisage a process in the attacking radical, derived from 2-iodocyclohexyl acetate, supplies a hydrogen atom and the decomposition of the phenyl iodine into a molecule of acetic acid, a molecule of benzene, and a new chain-carrying acetoxy radical. Hydrogenated radical could then react further to benzene by disproportionation, elimination, or donation of hydrogen to phenyl iodine or to acetoxy radicals.

**Free-Radical Reaction.** The other products in Table I, phenyl iodide, isomeric chloro-, and acetic acid, could be assigned to homolytic reactions such as eq 5-8. The presence of free

is indicated by the initiation of acrylonitrile polymerization, the presence of methyl radicals in styrene by the chlorotoluene isomer ratios which are close to those observed when di-*t*-butyl peroxide<sup>12</sup> or ethylmercuric iodide<sup>13</sup> is used as the radical

source. The homolysis of phenyl iodine diacetate to give two radicals (eq 5) is superficially like the first step in the homolysis of acetyl peroxide,<sup>14</sup> but the higher temperature required and the greater initial distance between the acetoxy radicals should greatly reduce the rate of geminate recombination. The total abstraction of ethane and methyl acetate is, therefore, in no way remarkable and does not necessarily mean that the acetoxy radicals are formed in separate steps.

**Acid-Induced Decomposition.** The substantial amount of acetic acid formed in the decomposition of phenyl iodine diacetate is very unlikely to come from

reaction of acetoxy radicals with the solvent. In the decomposition of acetyl peroxide in isooctane, no more than 1% of the acetoxy radicals react in that way.<sup>14d</sup> Alternative explanations for the acetic acid are induced decomposition *via* eq 8,<sup>15</sup> eq 9-10, or eq 11. Induced

decomposition according to the sequence 5-8 with either eq 9-10 or 11 as the chain-breaking steps would give a first-order and kinetically undetectable contribution to the rate law. The first-order rate constants in Table II do not appear to be very sensitive to the initial concentration of phenyl iodine diacetate, but since the total participation of homolytic processes is only 25%, a small contribution from reactions of other than first order could easily escape detection.

Table II. Effect of Initial Concentration of Phenyl Iodine Diacetate on Rate in Chlorobenzene<sup>a</sup> at 126.8°

$10^3 \times$ $C_0, M$	$10^3 \times$ $k, \text{sec}^{-1}$	$10^3 \times$ $C_0, M$	$10^3 \times$ $k, \text{sec}^{-1}$
3.05	7.16	25.76	7.46
7.39	7.38	36.44	6.67
16.72	7.70	45.31	6.61
20.96	7.68	23.02	7.57 <sup>b</sup>

<sup>a</sup> With 0.1 *M* acetic anhydride. With less acetic anhydride the rates are not reproducible unless elaborate precautions are taken to ensure dryness. Runs in ordinary solvent without added anhydride start with a very high rate constant, decreasing later in the run to that obtained in the presence of anhydride. The initial fast reaction is also suppressed by added acetic acid. The rate constant is the same as that for the reaction in the presence of acetic anhydride.

<sup>b</sup> With 0.2 *M* acetic anhydride.

The potential chain inhibitors, trinitrobenzene and iodine, appeared to accelerate the decomposition slightly,<sup>16</sup> though only by 15% or less. Styrene, like cyclohexene, caused an increased rate late in the run but had no effect on the initial rate. Diethyl ether (0.14 *M*) had no effect. On the other hand the addition of di-*t*-butyl peroxide as an independent source of methyl radicals gave a pronounced acceleration (Figure 3).

Benzoic anhydride in chlorobenzene causes an accelerated first-order decomposition of phenyl iodine diacetate after a short delay during which the reaction apparently proceeds at about its normal rate (Figure 4). This behavior is very much like the effect of benzoic anhydride on the decomposition of phenyl iodine dibenzoate<sup>3a</sup> except that the final value of the rate constant is  $19.0 \times 10^{-6} \text{ sec}^{-1}$  instead of the  $61 \times 10^{-6} \text{ sec}^{-1}$  obtained in the case of the dibenzoate. In the latter investigation it was demonstrated that benzoic anhydride trapped some intermediate quantitatively, eventually producing a critical concentration of a chain-transfer agent responsible for the accelerated reaction. A possible explanation for the acceleration of the decomposition of the diacetate by benzoic anhydride is

(15) A similar explanation has been suggested by Lorand for the formation of acetic acid (23 mole %) in the decomposition of *t*-butyl peracetate in chlorobenzene at 140°: J. P. Lorand, Dissertation, Harvard University, 1964.

and M. Szwarc, *J. Am. Chem. Soc.*, 76, 5981 (1954).

Figure 3. Effect of added di-*t*-butyl peroxide ( $3.55 \times 10^{-3} M$ ) on the rate of decomposition of phenyl iodine diacetate ( $21.9 \times 10^{-3} M$ ) in chlorobenzene at  $126.8^\circ$ .

Figure 4. Effect of added benzoic anhydride on the rate of decomposition of phenyl iodine diacetate at  $126.8^\circ$ : ●,  $C_0$  0.0241 *M*, benzoic anhydride 0.050 *M*, ordinary solvent; ○,  $C_0$  0.0216 *M*, benzoic anhydride 0.070 *M*, very carefully dried solvent.

again the trapping of some intermediate, presumably iodine acetate, with the formation of a slightly different chain-transfer agent. However, exchange of acetate and benzoate groups cannot be ruled out.<sup>17</sup>

Another probable instance of induced decomposition is the rapid reaction at room temperature between the diacetate and cyclohexene in undegassed chlorobenzene solutions. This reaction takes place with or without acetic anhydride, and loss of oxidizing titer is complete within 48 hr. Phenyl acetate is no longer detectable, and the major products are acetic acid, iodobenzene (100%), 2-cyclohexen-1-one (42% based on the phenyl iodine diacetate), 2-cyclohexen-1-ol (16%), and cyclohexene oxide (3.6%).<sup>18</sup>

**Substituent Effects.** Table III shows the effects of *meta* and *para* substituents on the rate of decomposition of phenyl iodine diacetate at two temperatures. Log *k* is correlated with  $\sigma$ , the  $\rho$  value being about 0.8 at  $126.8^\circ$ ,

(17) A reverse experiment by W. J. Mitchell (this laboratory) in which a 0.005 *M* solution of phenyl iodine dibenzoate was decomposed in the presence of 0.01 *M* acetic anhydride in chlorobenzene at  $126.8^\circ$  gave an initial fast reaction consuming about 10% of the oxidizing titer, then a first-order rate constant of  $13 \times 10^{-4} \text{ sec}^{-1}$ . The reaction was followed to 50% completion, well past the usual time for acceleration in an ordinary run using phenyl iodine dibenzoate in the presence of 0.01 *M* benzoic anhydride.

(18) These yields are from an experiment with 0.125 *M* phenyl iodine diacetate and 4.88 *M* cyclohexene in benzene as solvent to facilitate separation of the cyclohexene oxide.

Figure 5. Decomposition of three aryl iodine diacetates illustrating curvature of first-order rate plots when electron-releasing substituents are present.

but even this rather rough correlation requires the exclusion of *para* substituents capable of strong resonance interactions, whether electron donating or electron withdrawing. Neglecting the contribution from the homolytic part of the reaction for the moment, the observed first-order rate constants should be functions of  $k_1$  and  $k_{-1}$ , rate constants for the ionization and recombination steps of eq 1, and  $k_2$ , the rate constant

Table III. Rate Constants<sup>a</sup> for the Decomposition of Substituted Phenyl Iodine Diacetates in Chlorobenzene<sup>b,c</sup>

Substituent	$10^4 \times k, \text{ sec}^{-1}$	
	$126.8^\circ$	$150.1^\circ$
<i>p</i> -Methoxy	1.59	13.6
<i>p</i> -Fluoro	1.78	
<i>p</i> -Methyl	4.20	30.5
<i>p</i> -Phenyl	4.35	52.5
Hydrogen <sup>d</sup>	7.24 <sup>d</sup>	60.9
<i>m</i> -Chloro	10.5	106
<i>p</i> -Chloro	6.19	49.5
<i>m</i> -Nitro	21.1	201
<i>p</i> -Carbomethoxy	42.3	389

<sup>a</sup> In view of the complexity of the reaction, the activation parameters are of no theoretical significance. <sup>b</sup> The solvent contained acetic anhydride, 0.1 *M*. <sup>c</sup> Initial concentrations were usually in the range 0.02–0.03 *M*. <sup>d</sup> Mean of seven runs in Table II.

for the nucleophilic displacement step. Since the iodine-oxygen bonds in the diacetate are already quite

$$k_{\text{obsd}} = k_1 k_2 / (k_2 + k_{-1}) \quad (12)$$

polar, only a small negative value of  $\rho$  is expected for the ionization equilibrium. The net effect should be dominated by the positive  $\rho$  of the nucleophilic displacement.<sup>19</sup> A further source of complexity in the substituent effects is variation in the relative rate of the homolytic part of the reaction. As can be seen in Figure 5, runs in which the substituent is electron releasing show a distinct increase in first-order rate constant in the latter part of the reaction.<sup>20</sup> The electron-releasing substituents may not decelerate the homolytic reaction,

(19) A different relative importance of inductive and resonance effects in the two steps would seriously perturb any simple free-energy relationship involving  $k_{\text{obsd}}$ : J. E. Leffer and E. Grunwald "Rates and Equilibria of Organic Reactions," Interscience Publishers, Inc., New York, N. Y., 1963.

(20) In such cases the tabulated rate constants are initial values.

particularly the induced part, to the same extent as the ion-pair reaction. If the homolytic reaction gives rise to any cyclohexadienes,<sup>11</sup> their reaction with iodine acetate should give an efficient chain-transfer agent comparable to 2-iodocyclohexyl acetate. Whatever the explanation for the autocatalysis, the products from the *p*-fluoro derivative clearly indicate a decreased relative rate for the ion-pair part of the reaction. The yields per mole of diacetate were as follows: methyl iodide, 37.4%; acetic acid, 27.6%; *p*-fluoriodobenzene, 54.1%; and *p*-fluorophenyl acetate, 48.0%.

## Experimental Section

**Chlorobenzene** was stirred with three portions of sulfuric acid and washed with water and sodium bicarbonate solution. After successive 24-hr periods of drying with  $\text{CaCl}_2$ , anhydrous  $\text{CaSO}_4$ , and  $\text{P}_2\text{O}_5$ , it was distilled from  $\text{P}_2\text{O}_5$  through a 35-in. column packed with 0.25-in. glass helices. A middle fraction, bp 131.1–132.1°, was collected.

**Acetic anhydride** was distilled through the glass helices column. After a large forerun, a middle fraction, bp 139.0°, was collected.

**Cyclohexene** (bp 83.1–83.5°) was refluxed over Na in a nitrogen atmosphere. Samples were taken off as needed by distillation through a 1-ft glass helices column. Cyclohexene exposed to the air for 2 days gave a positive peroxide test.

**Benzoic anhydride** (mp 40.0–41.5°) was twice recrystallized from benzene and petroleum ether (bp 60–70°). It was shown by infrared spectroscopy to be free from benzoic acid.

**Aryl Iodine Diacetates.** The substituted phenyl iodine diacetates were prepared by a procedure like that given for *m*-chlorophenyl iodine diacetate (see Table IV for melting point data).

Soc.*, 107 (1953). <sup>e</sup> Lit.<sup>4</sup> gives 107°. <sup>f</sup> C. H. C. Willgerodt, "Die Organischen Verbindungen mit Mehrwertigem Jod," F. Enke, Stuttgart, 1914. <sup>g</sup> Lit.<sup>7</sup> gives 155°. <sup>h</sup> Lit.<sup>7</sup> gives 140°; J. G. Sharfkin and H. Saltzman, *Anal. Chem.*, 35, 1428 (1963). <sup>i</sup> Lit.<sup>4</sup> gives 104°. <sup>j</sup> Lit.<sup>7</sup> gives 155°. <sup>k</sup> Lit. gives 158°; I. Lillien, *J. Chem. Soc.*, 4498 (1962).

***m*-Chlorophenyl Iodine Diacetate.** To 23.8 g (0.1 mole) of *m*-chloriodobenzene was added dropwise with stirring 31 ml (0.24 mole) of 40% peracetic acid. The flask was chilled with an ice-water bath during the slow addition (1 hr). Two phases separated, but on continued stirring the solution became homogeneous. The solution was stirred for an additional hour at 20–25° and then cooled in an ice-salt bath. The white crystals which formed were washed quickly with ice-cold water. (Warm water may cause hydrolysis of the diacetate to the aryl iodine oxide, particularly in the case of the *p*-methoxy-substituted compound.) The crystals were pressed dry and dried overnight *in vacuo* over  $\text{P}_2\text{O}_5$ . (The use of  $\text{CaCl}_2$  instead of  $\text{P}_2\text{O}_5$  caused the crystals to turn yellow.) Recrystallization was effected from a minimum amount (1.5 ml/g) of 1:4 acetic anhydride-acetic acid, yield, 22.5 g (63%); mp 154.5–156.5° (lit.<sup>11</sup> 154°). Pure dry benzene (10 ml/g) could also be used for the recrystallization.

**Kinetic Procedure.** At no time was the purity of the aryl iodine esters used in the kinetic runs less than 98.5%. Standard solutions

in chlorobenzene were checked by iodometric titration before a run was started.

Kinetic runs were made in 18 × 150 mm test tubes fitted with a standard taper, ground glass joint. The tubes were cleaned with hot chromic acid cleaning solution and rinsed repeatedly with water, dilute ammonium hydroxide, water, and distilled water. The tubes were oven dried and a constriction was added for sealing. Before use, the tubes were fitted to a vacuum system and leak tested with a Tesla coil.

The tubes were flushed with prepurified<sup>22</sup> nitrogen, and aliquots of the diacetate solution were added to each tube from a calibrated pipet. Each tube was then attached to the vacuum system and put through a four-cycle freeze-degas-thaw procedure. The final pressure in the vacuum system was less than 0.005 mm. The tubes were sealed and removed for use or storage at 5°. Kinetic runs using tubes degassed fewer than three times were usually not reproducible.

For the experiments with "carefully dried solvent" aliquots of diacetate solutions were pipetted into standard constricted tubes. These tubes and unconstricted tubes containing phosphorus pentoxide were attached to the vacuum line. The chlorobenzene was degassed three times, distilled into the phosphorus pentoxide tube, allowed to stand for 1 hr at room temperature, and redistilled into the original tube. After one more degassing cycle, the tube was sealed. For experiments with cyclohexene, the constricted tubes were fitted with a rubber serum cap and the cyclohexene was injected with a syringe just before the last degassing cycle.

Normally, eight tubes were used in each kinetic run. Since the half-life for the decomposition of phenyl iodine diacetate at 126.8° in chlorobenzene is about 24 hr, the warm-up period for the tubes is insignificant and the zero point was determined from an aliquot of the prepared solution. This also provided a constant check on diacetate purity.

For short runs (ca. 6 hr or less), all tubes were placed in the bath and the zero-point tube was removed when the temperature of the bath returned to equilibrium. An accurate account of the temperature was kept by a thermistor-Wheatstone bridge-recorder arrangement.<sup>24</sup> During the shorter runs, tubes were quenched in ice water.

For analysis the contents of the tubes were decanted and rinsed out with two 1-ml portions of pure chlorobenzene. The concentration of diacetate was determined by iodometric titration:<sup>25</sup> (1) add 10 ml of fresh acetic acid (acetic acid left exposed to the air gives high blank values), (2) add pellets of carbon dioxide to the flask and at the same time to 25 ml of distilled water, (3) prepare a fresh solution of saturated potassium iodide and add 3 ml to the flask, (4) swirl the flask and add the deaerated water, (5) titrate immediately to a starch-iodine end point with approximately 0.015 to 0.10 *N* sodium thiosulfate using a magnetic stirrer for mixing. This titration occurs in a two-phase system; however, excellent results have been obtained with both benzene and chlorobenzene solutions of the diacetate. The use of acetic acid as a solvent for iodometric titrations has been criticized<sup>26</sup> but titrations of benzene solutions of freshly recrystallized benzoyl peroxide showed purities greater than 99%.

**Product Analysis.** Phenyl iodine diacetate was weighed into a modified Pyrex hydrogenation bomb (A) and the constriction rinsed clean with a few milliliters of chlorobenzene. Approximately 300 ml of purified chlorobenzene was added to a second bomb (B) along with several grams of phosphorus pentoxide and a magnetic stirring bar. The entire apparatus was attached to a vacuum system and bomb B was degassed using a three-cycle freeze-degas-thaw procedure. The solution was stirred for 1 hr at room temperature at the end of the third cycle. Bomb A was then cooled with liquid nitrogen and the chlorobenzene in bomb B allowed to distil into bomb A. Stirring was continued to prevent bumping. After all the liquid had been distilled, the system was degassed twice more and the constriction sealed with a flame. The bomb was then placed in the thermostated bath.

After about ten half-lives, the bombs were removed, cooled, wiped clean, and attached to the vacuum system. After the system was evacuated, the capillary tip was broken, and the gases were allowed to distil into the liquid nitrogen trap. The bomb was re-

(23) Minimum purity: 99.997%; dew point: -85°F, contains 8 ppm oxygen.

(24) This apparatus was designed and built by Mr. Vern Champeaux.

frozen with Dry Ice-isopropyl alcohol and the pressure of the non-condensable gases recorded. The liquid nitrogen bath was removed and the total gas pressure recorded.

The gases were thoroughly mixed using a Toepler pump and then forced by external pressure into a gas sampler fitted with a rubber serum cap. A gas-tight Hamilton syringe was used to transfer the gas mixture to a F & M Model 700 gas chromatograph with a thermal conductivity detector.<sup>27</sup> Air, methane, ethane, and carbon dioxide are easily resolvable and a check was made of their separation before an unknown was measured.

After the sample had been removed, the system was evacuated and the bomb degassed a second time. The pressure was measured and added to the first pressure reading. The system was reevacuated and the total volume calculated by admitting a known volume of gas at atmospheric pressure and observing the final pressure.

The Dry Ice-isopropyl alcohol trap was rinsed with chlorobenzene and the washings were added to the main solution. For qualitative identification the solution was distilled and three fractions were collected; a 5-ml forerun, bp 25–130°; ca. 300 ml of chlorobenzene, bp 130°; and a high boiling residue (ca. 20 ml). Each of the fractions was subjected to gas chromatography (10 ft × 0.25 in. SF-96 silicone oil, 7 ft × 0.25 in. DEGS,<sup>28</sup> 7 ft × 0.25 in. PPE,<sup>29</sup> and 7 ft × 0.25 in. FFAP<sup>30</sup> columns). Peaks were collected

and identified by comparing their infrared and nmr spectra and gas retention times with those of authentic samples.

Quantitative measurements were performed using standard solutions of known compounds. Each peak was bracketed by injecting enough of the standard solutions so that both a smaller and a larger peak than that of the unknown compound was obtained. Analyses were made using the same chromatographic conditions. All analyses were made in duplicate.

No low-boiling compounds other than methyl iodide were observed. Methyl acetate was found to be completely resolved from methyl iodide at 35° using a 7 ft × 0.25 in. DEGS column; it was not present in the product mixture.

No high-boiling compounds other than those mentioned were detected. Biphenyl, phenol, *o*- and *m*-iodochlorobenzene, *o*-iodophenyl benzoate, *p*-chlorobenzyl acetate, and *p*-chlorophenyl acetate were shown to be absent (or if present, in less than 1% yield) by control experiments.

**Determination of Chlorotoluene Isomer Ratios.** The chlorotoluene isomer ratios were determined by gas chromatography, using the liquid crystal technique recently developed by Dewar and Schroeder<sup>31</sup> and an F & M Model 700 flame ionization chromatograph at 125°. Peak height-to-composition conversion factors were determined experimentally for each isomer.

## Decarbonylation of Aromatic Carbonyl Compounds Catalyzed by Rhodium Complexes

Jochanan Blum,<sup>1</sup> Edna Oppenheimer, and Ernst D. Bergmann

*Contribution from the Department of Organic Chemistry, Hebrew University, Jerusalem, and the Institute for Advanced Study, Princeton, New Jersey.*

*Received December 29, 1966*

**Abstract:** The catalytic decarbonylation of aryl chlorides, bromides, and cyanides with chlorotris(triphenylphosphine)rhodium(I) has been investigated; particular attention has been paid to polycyclic aryl halides. A theory of the mechanism of decarbonylation has been suggested which accounts for the observations made in this study. The essential features of the theory are the formation of V, its isomerization to VI, and the loss of carbon monoxide from the latter. Several new rhodium complexes are described.

A previous communication from this laboratory<sup>2</sup> reported that chlorotris(triphenylphosphine)rhodium(I) catalyzes the decarbonylation of aryl chlorides to the corresponding aryl chlorides. Almost simultaneously, Tsuji and Ohno observed that aliphatic acyl chlorides are converted, under the same conditions, into olefins.<sup>3</sup> In both cases, the analogous response of acyl bromides was briefly mentioned.<sup>3,4</sup>

The Japanese authors suggested a mechanism for these decarbonylation reactions. This mechanism will have to be somewhat modified in view of the more extensive studies reported in the present paper.

In Table I, the results obtained with a number of benzoyl chlorides are summarized. This table also

contains some examples for the decarbonylation of benzoyl and naphthoyl bromides. The last two examples in this table indicate that carbon monoxide can be extruded also from benzylic carbonyl chlorides without difficulty.<sup>2,3</sup> It is obvious from these data that the reaction is practically unaffected by electronic or steric influences of substituents; the seemingly accelerating effect of the  $\alpha$ -naphthoyl residue (compare benzoyl and  $\alpha$ -naphthoyl bromide) is most probably due to the higher temperature at which the reaction with  $\alpha$ -naphthoyl bromide is carried out.

The behavior of the three isomeric phthaloyl chlorides deserves some comment. *o*-Phthaloyl chloride does not react at all, possibly because it has the structure of  $\alpha,\alpha$ -dichlorophthalide.<sup>5</sup> The other two isomers decompose in two distinct steps, *via* the chlorobenzoyl chlorides, into the dichlorobenzenes. This is in

<sup>a</sup> "Ring Index" numbering. <sup>b</sup> And 30% of ketone X.

marked contrast to the behavior of the benzenedisulfonyl chlorides.<sup>4</sup>

The very low yields obtained with *p*-acetamidobenzoyl chloride are due to the very pronounced instability of the aroyl halide at the required elevated temperature.

In the decarbonylation of relatively low-boiling aroyl chlorides it has proven essential to distil off the aryl chloride as it is formed; otherwise the reaction comes to a standstill after a given period, which varies from compound to compound. As examples, *o*-, *m*-, and *p*-chlorobenzoyl chlorides, heated with a small amount (100 mg/9.9 g) of I at 217°, cease to react after 300, 40, and 10 min, respectively (the yield of the three dichlorobenzenes after these periods was 8.0, 15.3, and 1.7%, respectively). Here an influence of the distance of the carbonyl group from the substituent appears to exist. Following the theoretical concept outlined below, we assume that a rhodium complex is formed which does not participate in the decarbonylation reaction. Whatever the structure of the complex is, it must be assumed that it is stable in the presence of aroyl halides.

The "distillation technique" is not applicable to the preparation of the otherwise difficultly obtainable halogenated polycyclics in which we were particularly interested in connection with other projects of this laboratory. This is due to the relative instability of the polycyclic acid halides at elevated temperatures and the difficulty in obtaining these halides free from impurities, e.g., hydrogen halide. We shall return to this point later on; here it may be said that an easy technique has been developed for the polycyclic acyl halides. They are heated at about 260° for 1–3 min in the presence of I, and the product is purified by chromatography on alumina. The results are summarized in Table II, from which it can be seen that this technique gives, e.g., for 1-pyrenoyl chloride a yield of 94%, while the

"distillation technique" at 230° (8–10 min) gave only 40% of 1-chloropyrene.

Table III shows some experiments with aroyl cyanides which are also decarbonylated by heating with I, yielding the nitriles of aromatic acids. This is perhaps not surprising in view of the "pseudo-halogen" character of the cyano group. Table III contains, for comparison, also two examples for the decarbonylation of aldehydes. The stoichiometric decarbonylation of aldehydes by the reaction with I has, of course, been known before.<sup>6</sup>

**Table III.** Decarbonylation of Aroyl Cyanides and Aldehydes

Aromatic carbonyl compd	Reaction time, hr	% Yield of nitrile or hydrocarbon
$C_6H_5COCN$	<i>a</i>	<i>a</i>
$4-ClC_6H_4COCN$	3.5	95
$\alpha-C_{10}H_7COCN$	1	87
$\alpha-C_{10}H_7CHO$	2	88
$\beta-C_{10}H_7CHO$	2.5	77

<sup>a</sup> Very slow decarbonylation. After 7 hr, 8% of benzonitrile and 91% of unchanged starting material were obtained.

Tsuji and Ohno<sup>3</sup> have assumed that the essential intermediate in the decarbonylation reaction is chlorocarbonylbis(triphenylphosphine)rhodium(II). As we shall show, this complex has a part in the scheme of the reaction, but it cannot always be an essential intermediate; it is often much less reactive as a decarbonylation catalyst than I.  $\alpha$ -Naphthoyl chloride is converted at 290° into  $\alpha$ -chloronaphthalene by II in 30, and by I

(6) J. Tsuji and K. Ohno, *Tetrahedron Letters*, 3969 (1965).

in 7 min. Furthermore, one would have to assume that II is converted, at least initially, into a complex of type III; however, we have not been able to isolate such a complex or even detect its temporary appearance by its characteristic infrared spectrum.

We propose that compound I is first converted into the dimeric tricoordinate complex IV described by Bennett and Longstaff.<sup>7</sup> This complex reacts with the aroyl chloride to give V, which isomerizes to VI. The next step is normally the loss of carbon monoxide, leading to VII, followed by the elimination of aryl chloride. Thus IV is regenerated and the catalytic activity of IV (and, therefore, I) is explained. As a side reaction, the steps of the decomposition of VI can be reversed: elimination of the aryl chloride leads to II and subsequent liberation of carbon monoxide back to IV. This would be the mechanism proposed by Tsuji and Ohno<sup>3</sup> and, as already pointed out, cannot be the major component of the scheme.

In no case have we been able to isolate and identify all the intermediary stages demanded by the proposed reaction mechanism. It seems, however, supported by the observations described in the following paragraphs. When some of the substituted benzoyl chlorides, e.g., *p*-chlorobenzoyl chloride, were heated very briefly with I, yellow rhodium complexes were obtained (not isolated in analytical purity) which did not show any carbonyl absorption in the infrared and are, very likely, of type VII. Benzoyl, *m*-toluoyl, and *m*-chlorobenzoyl chloride as well as *p*-bromobenzoyl bromide gave at 80 and at 200° the same type of complex, which showed no absorption characteristic of an aroyl group, but metal carbonyl peaks (in Nujol) at 2068, 2058, 2070, and 2055 cm<sup>-1</sup>, respectively, indicating that the complexes are of formula VI. In analogous cases<sup>4,8</sup> such carbonyl peaks have been observed at 2080 and 2072 cm<sup>-1</sup>. On the other hand,  $\alpha$ -naphthoyl chloride forms, even at 250°, a complex (or rather a mixture of two isomeric complexes) which shows carbonyl absorption at 1670 and 1685 cm<sup>-1</sup>,  $\alpha$ -naphthoyl bromide gives a complex with a peak at 1675 cm<sup>-1</sup>, and *o*-chlorobenzoyl chloride, a rather unstable complex with carbonyl bands at 1675 and 1715 cm<sup>-1</sup>. These complexes represent examples for type V.

In one case—using  $\beta$ -naphthoyl chloride in boiling benzene—we have followed the transition from an iso-

meric mixture of pentacoordinate complexes of type V (aryl carbonyl absorptions at 1665 and 1680 cm<sup>-1</sup>) to VI (Ar =  $\beta$ -C<sub>10</sub>H<sub>7</sub>), showing a characteristic metal carbonyl band at 2062 cm<sup>-1</sup>.

We have also observed transitions from complexes V and VI to II, though these transitions have often been erratic in their reproducibility. When hexane or ethanol was added to a benzene solution of VI (Ar = C<sub>6</sub>H<sub>5</sub>),<sup>8</sup> II precipitated often, but not always, in quantitative yield.<sup>2</sup> Heating of VI (Ar = C<sub>6</sub>H<sub>5</sub>) *in vacuo* (20 mm) for 4.5 hr at 144° did not produce any changes, while refluxing with xylene for 3 min caused complete conversion into II.

In many experiments leading to II, the latter was isolated as a mixture of two isomeric forms, exhibiting carbonyl absorption at 1965 and 1978 cm<sup>-1</sup>; the melting points of the isomers were 204–205° and 209–210°, respectively. Previous authors<sup>6,9</sup> reported for II an unsharp melting point around 195° and a carbonyl absorption at 1980 cm<sup>-1</sup>. As the compound absorbing at 1965 cm<sup>-1</sup> predominates in these mixtures it is assumed—in accord with similar cases studied previously<sup>8,10</sup>—that it has the *trans* structure (mp 209–210°), while the minor isomer is assigned the *cis* configuration. Recently Chatt and Shaw reported that the *trans* isomer of II absorbs at 1961 cm<sup>-1</sup>, but indicated a melting point of 189–190.5°.<sup>11</sup> The pure *trans* form was isolated from  $\alpha$ -naphthaldehyde and I, the pure *cis* form, from 9-anthroyl chloride and I (after chromatography on neutral alumina); the former is partially isomerized to the latter by heating with chlorobenzene at 220° in a sealed tube. Incidentally, Tsuji and Ohno's<sup>3</sup> theory would imply that under these conditions II is converted into VI, which is, however, not the case.

Let us return to the reactions of polycyclic aroyl halides. It has been pointed out that their transformations are affected adversely by impurities. Moisture and hydrogen chloride may form the hydrido complex VIII<sup>8</sup> or compound IX (see Table IV) from I. VIII may also originate from V, by reaction with moisture:  $\text{V} + \text{H}_2\text{O} \rightarrow \text{ArCOOH} + \text{VIII}$ .

Both these complexes may catalyze formation of hydrocarbons from the aroyl chlorides; they may, alternatively, lose hydrogen chloride and cause Friedel-Crafts reactions. Such a reaction has, indeed, been observed in the case of 9-anthroyl chloride. Together with the expected 9-chloroanthracene, a ketone, C<sub>29</sub>H<sub>17</sub>ClO, was formed, showing a strong carbonyl absorption at 1645 cm<sup>-1</sup>. It is assigned structure X on the strength of two independent syntheses: from 9-chloroanthracene and 9-anthroyl chloride, or from anthracene and 10-chloro-9-anthroyl chloride.

It is noteworthy that 9-anthroyl chloride could only be decarbonylated with catalytic amounts of I above 300°. Below this temperature, a yellow complex of formula XI was obtained, which was also formed when the two reactants were refluxed in decalin for 1 hr. The structure is in accord with the existence of two carbonyl absorptions: 1680 cm<sup>-1</sup> (acyl carbonyl) and 2055 cm<sup>-1</sup> (metal carbonyl).

The analyses and some other data for the metal complexes isolated in this study are summarized in Table IV.

<sup>a</sup> Rh–H absorption at 2095  $cm^{-1}$ ; carbonyl band at 1960  $cm^{-1}$ . Cf. L. Vaska, *J. Am. Chem. Soc.*, **88**, 4100 (1966). <sup>b</sup> Cf. ref 8. <sup>c</sup> Not isomerically pure; contaminated with VI (Ar =  $\beta$ - $C_{10}H_7$ ); carbonyl bands at 1665 (vs), 1680 (vs), and 2062 (w)  $cm^{-1}$ . <sup>d</sup>  $\bar{\nu}_{CO}$  2062 (vs)  $cm^{-1}$ . <sup>e</sup> Recrystallized from a mixture of benzene–hexane.

In conclusion, some comment is due on the reaction of aroyl bromides (Tables I, II) with the chloro complex I. Experiments at relatively low temperatures have shown that in these reactions the original metal chlorine atom is partly or completely replaced by bromine. For example, *p*-bromobenzoyl bromide gave with I in boiling benzene (30 min) a complex which could be recrystallized from benzene–hexane, absorbed at 2055  $cm^{-1}$ , and had thus the structure XII, which is confirmed by the analysis. XII is thus an analog to the complex of type VI.  $\alpha$ -Naphthoyl bromide, under the same conditions, on the other hand, gave an orange five-coordinate complex, which after recrystallization from benzene showed aromatic carbonyl absorption (at 1675  $cm^{-1}$ ) and was thus XIII, corresponding to V.

## Experimental Section

The different techniques used for the decarbonylation reactions are illustrated by the following examples.

***m*-Dibromobenzene from *m*-Bromobenzoyl Bromide.** A mixture of 14.0 g of *m*-bromobenzoyl bromide (Eastman Organic Chemicals) and 50 mg of I was heated in a Claisen flask equipped with a 25-cm-long Vigreux column, so as to permit distillation of the dibromobenzene formed at 214–216°. After 1 hr the evolution of carbon monoxide practically ceased, and an additional portion of 15 mg of I was added to the reaction mixture. This process was repeated four times in intervals of 15 min (until decarbonylation was

complete). The crude distillate was washed with alkali, neutralized, and dried in the usual manner and redistilled at 215–216°, yielding 10.6 g (85%) of pure *m*-dibromobenzene.

**$\alpha$ -Naphthonitrile from  $\alpha$ -Naphthoyl Cyanide.** A mixture of 9.0 g of  $\alpha$ -naphthoyl cyanide (mp 101–102°; prepared by refluxing  $\alpha$ -naphthoyl chloride with an equal amount of cuprous cyanide at 190° for 1 hr) and 0.1 g of I was heated for 45 min in a Claisen flask, so that the product distilled off as formed (bp 294°). The product was distilled again (during 10 min) with 0.02 g of I. Thus 6.6 g (87%) of  $\alpha$ -naphthonitrile (mp 37°) was obtained. The nitrile was identical with an authentic sample.

**$\alpha$ -Chlorodiphenylmethane from Diphenylacetyl Chloride.** A quantity of 6.5 g of freshly distilled diphenylacetyl chloride [bp 185–187° (20 mm)] and 0.1 g of I were placed in a Claisen flask mounted with two thermometers and connected to a variable vacuum system. The mixture was heated at 210–230° (internal temperature), and a suitable vacuum was applied, so that the product distilled off during 15 min. On redistillation at 137–138° (2 mm) there was obtained 5.4 g (94%) of colorless  $\alpha$ -chlorodiphenylmethane, identical with a product prepared from benzhydrol.<sup>12</sup>

**6-Chlorobenzo[c]phenanthrene.** A mixture of 1.45 g of 6-benzo[c]phenanthroyl chloride<sup>13</sup> and 0.1 g of I was heated in a test tube, under exclusion of moisture, at 260° (internal temperature) for 1–3 min. After this time the evolution of carbon monoxide had ceased. Chromatography on alumina, *n*-hexane serving as eluent, yielded 1.15 g (89%) of 6-chlorobenzo[c]phenanthrene from *n*-hexane as colorless needles, mp 85–86°,  $\lambda_{max}^{E_{OH}}$  ( $m\mu$  (log  $\epsilon$ )) 219 (4.71), 232 (4.38), 245 (4.15), 276 (4.71), 285 (4.79), 310 (4.00), 318 (4.02), 330 (3.57), 361 (2.57), and 380 (2.38). *Anal.* Calcd for  $C_{18}H_{11}Cl$ : C, 82.4; H, 4.2; Cl, 13.4. Found: C, 82.2; H, 4.1; Cl, 13.5.

**Decarbonylation of 9-Anthroyl Chloride.** A quantity of 2.34 g of 9-anthroyl chloride was heated, in a test tube, with 0.1 g of I at 310° for 3 min. Chromatography on alumina, benzene serving as eluent, yielded, as the first fraction, 0.49 g (24%) of pale yellow 9-chloroanthracene (mp 102–104°) identical with the product prepared from anthracene and cupric chloride.<sup>14</sup>

A second fraction from the chromatography afforded, on recrystallization from benzene and ethanol, 0.60 g (30%) of X as deep yellow crystals, mp 260–262°. *Anal.* Calcd for  $C_{20}H_{17}ClO$ : C, 83.6; H, 4.1; Cl, 8.5; mol wt, 416. Found: C, 83.8; H, 4.1, Cl, 8.9; mol wt, 416 (mass spectrum).

**9-Anthryl 10-Chloro-9-anthryl Ketone (X) by Friedel–Crafts Acylation.** a. Following the known route for the preparation of 9-benzoylanthracene, 2.8 g of 9-chloroanthracene, 3.5 g of 9-anthroyl chloride, 1.8 g of aluminum chloride, and 50 ml of carbon disulfide were refluxed for 48 hr. After the usual work-up, the oily residue was chromatographed on alumina, yielding 0.8 g of X, mp 260–262°.

b. In a similar manner, anthracene and 10-chloro-9-anthroyl chloride were treated with aluminum chloride in carbon disulfide, giving X in 21% yield, identical with the samples obtained by the two preceding methods.

## Mechanism of Cyclodehydration of 2-Phenyltriarylcarbinols

Harold Hart and Edward A. Sedor

Contribution from the Department of Chemistry, Michigan State University, East Lansing, Michigan 48823. Received January 19, 1966

**Abstract:** A kinetic study of substituent effects on the acid-catalyzed cyclodehydration of 2-phenyltriarylcarbinols to the corresponding 9,9-diarylfluorenes reveals that the rate-determining step depends on the nature of the substituents. A Hammett plot shows a sharp concave downward break. One group of carbinols have rates which correlate best with  $\sigma$ , have a large negative  $\rho$  ( $-2.51$ ), and show a strong rate dependence on solvent acidity, a threefold rate enhancement in deuterated solvent, and an activation entropy near zero or slightly positive. The remaining carbinols have rates which correlate best with  $\sigma^+$ , have a large positive  $\rho$  ( $+2.77$ ), are insensitive to the solvent acidity, show no marked rate effect in deuterated solvent, and have a rather large negative activation entropy. These observations are rationalized by a three-step mechanism: (1) rapid and reversible protonation of the carbinol, (2) dissociation to the corresponding triarylcarbonium ion, and (3) intramolecular electrophilic substitution on the 2-phenyl ring. Step 2 is rate determining for carbinols on the negative  $\rho$  correlation line; step 3 is rate determining for carbinols on the positive  $\rho$  correlation line.

Attempts to convert triarylcarbinols with a 2-phenyl substituent in one of the aryl rings to the corresponding carbonium ion by dissolution in acid generally lead instead to a substituted fluorene, by cyclodehydration.<sup>1</sup> An analogous reaction has been observed with diaryl,<sup>2</sup> and monoaryldialkylcarbinols,<sup>3</sup> as well as with 2-benzyl,<sup>4</sup> 2-phenoxy,<sup>5</sup> or 2-thiophenoxytriarylcarbinols.<sup>6</sup> For example, Clarkson and Gombert,<sup>1</sup> who were the first to isolate pure, crystalline 2-phenyltriphenylcarbinol, found that all attempts to convert it to the corresponding chloride gave instead a quantitative yield of 9,9-diphenylfluorene. Although this type of reaction has been known for over 60 years, its mecha-

nism has not been examined in detail. Presumably a reaction sequence such as 1-3 is followed, but the

kinetics have not been studied. The reaction has interesting aspects. For example, if  $k_2$  were rate

determining, the reaction would be analogous to an  $\text{S}_{\text{N}}1$  solvolysis, with the aromatic ring serving as a built-in nucleophile. On the other hand, if  $k_3$  were rate determining, the reaction would be comparable to other electrophilic aromatic substitutions, but with the electrophile and substrate built into the same reactive intermediate. Substituents might be expected to alter the relative rates of the various steps.

With a view to examining these alternatives, we synthesized a number of carbinols of the type shown (1-12) and found suitable conditions for carrying out

1-12  
(for X, Y, and Z see Table I)

the cyclizations at measurable rates. The reaction rates were followed spectrophotometrically. A study of the effect of substituents on the reaction rates, of activation parameters, of effect of solvent acidity on the rates, and of solvent deuterium isotope effects allows a fairly complete mechanistic picture to be presented.

## Results

The required carbinols were prepared either by reaction of a substituted phenyl Grignard reagent with 2-benzoylbiphenyl, or by reaction of the Grignard reagent from 2-bromobiphenyl with a disubstituted benzophenone. Formulas of the 12 carbinols studied and their relative rates of cyclodehydration are given in Table I listed in order of decreasing  $\sigma$  values of the substituents. Physical constants of the carbinols are given in Table VI and complete rate data are given in Table VIII in the Experimental Section.

Required samples of the cyclodehydration products were obtained by adding a few drops of strong acid to a refluxing solution of the carbinol in acetic acid. Upon cooling, nearly quantitative yields of the crystalline disubstituted fluorenes were obtained. They are

listed, with their properties, in Table VII in the Experimental Section.

The cyclization rates of the carbinols were determined in 80% aqueous acetic acid containing 4 wt % of sulfuric acid. The choice of this rather unconventional medium was dictated by the need to strike a balance between measurable rates and solvents in which both the starting carbinol and the product hydrocarbon were soluble. For some carbinols, the amount of sulfuric acid was varied (4-6%). The reactions were studied at five temperatures between 15 and 35°. Progress of each reaction was followed by the appearance of a band in the vicinity of 308 m $\mu$  which was present in the fluorenes, but absent in the carbinols. In several cases (2, 6, and 10) a comparison of the product isolated from a kinetic run with that synthesized independently showed that the reaction proceeded quantitatively to completion, without formation of side products.

All of the reactions followed precise first-order kinetics through at least 88% reaction. The rate data are given in Table VIII in the Experimental Section, and the derived activation parameters are listed in Table I. The reaction rates were independent of initial carbinol concentration, tested with two different substrates (Table II).

Certain of the carbinols (9-12) gave colored solutions in the reaction medium. In these cases, it was possible to follow not only the appearance of product (at  $\sim$ 308 m $\mu$ ) but also the disappearance of the visible peak (at  $\sim$ 470 m $\mu$ ) due to the carbonium ion. The rates of the two processes were identical within experimental error (Table III).

## Discussion

**Hammett Correlations.** It is clear from the data presented in Table I that substituents markedly affect the cyclodehydration rates, but that their effect does not follow a single Hammett plot. The fastest reaction occurred with two *p*-CH<sub>3</sub> substituents, and the slowest with two *p*-OCH<sub>3</sub> substituents, whereas compounds with one or two *p*-Cl substituents reacted at intermediate rates. The substituents in fact fall into two groups. One of these is best correlated by Hammett  $\sigma$  values, the value of  $\rho$  at 25° being -2.51. The correlation coefficient is 0.990, as contrasted with 0.955 if  $\sigma^+$  values are used.<sup>7</sup> A plot of  $\log k$  vs.  $\sigma$  for these substituents is shown in the right portion of Figure 1. Those carbinols which have a *p*-OCH<sub>3</sub> substituent fall nowhere near the correlation line, and in fact fall into the second group of substituents, which are best correlated by  $\sigma^+$ , with a value of  $\rho$  at 25° of +2.67 and a correlation coefficient of 0.976.<sup>8</sup> Carbinol 10, with two *p*-methyl substituents, occupies an ambiguous position at the apex of Figure 1. The two points shown for this carbinol correspond to the use of  $\sigma$  or  $\sigma^+$  constants, and the compound falls reasonably close to both correlation lines.

The activation parameters (Table I) also fall into two groups. For those substituents on the negative  $\rho$  correlation line, the activation enthalpies decrease as the electron-donating power of the substituents increases, and the activation entropy is on the whole near zero or slightly positive. Conversely, for those substituents on the positive  $\rho$  correlation line, the activation enthalpies increase as the electron-donating power of substituents increases, and the activation entropy is moderately

(7) Using  $\sigma^+$ ,  $\rho$  was -1.94.

(8) Using  $\sigma$ , the correlation coefficient was 0.801 and  $\rho$  = +7.79.

Figure 1. Hammett plot for the cyclodehydration of 2-phenyltriarylcarbinols in 80% aqueous acetic acid containing 4% sulfuric acid at 25°. Numbers refer to the formulas in the text.

large and negative. A plot of  $\Delta H^\ddagger$  vs.  $\Delta S^\ddagger$  for either set of substituents shows a rather large degree of scatter. The best straight lines drawn through each set lead to isokinetic temperatures well above the temperatures of the kinetic measurements.

**Mechanism.** Leffler and Grunwald<sup>9</sup> have pointed out that a Hammett plot which shows a concave downward break (Figure 1) is caused by a change in the rate-determining step of an otherwise constant mechanism. This is consistent with sequence 1–3, in which step 2 is rate determining for those substituents which appear on the right side of Figure 1, and step 3 is rate determining for those substituents which appear on the left side of Figure 1. Thus the ionization step is normally rate determining, but when the substituents stabilize the intermediate carbonium ion sufficiently, ring closure becomes rate determining.

The signs and magnitudes of the  $\rho$  values, the substituent correlations (*i.e.*,  $\sigma$  or  $\sigma^+$ ), and the activation parameters are in accord with this interpretation. When step 2 is rate determining, the transition state will be electron deficient with respect to the ground state, and a negative  $\rho$  is expected. However, since formation of  $R^+$  is undoubtedly not complete at the transition state,  $\rho$  should be less negative than  $-3.64$ , the value observed<sup>10</sup> for the equilibrium ionization of triarylcarbinols. The observed  $\rho$  of  $-2.51$  is thus reasonable. The better agreement with  $\sigma$  rather than  $\sigma^+$  indicates that direct resonance interaction of the substituents in 1–8 with the cationic center is small. Actually the correlation is not highly sensitive to the difference between  $\sigma$  and  $\sigma^+$  (0.990 vs. 0.955), possibly because the sub-

stituents are mainly electron withdrawing on the right side of Figure 1. Also, because of the 2-phenyl substituent, the transition state may be sufficiently non-planar as to minimize the importance of a resonance effect. The small, slightly positive activation entropy is consistent with decreased crowding accompanying the change from  $sp^3$  to  $sp^2$  hybridization at the ionization site.

For those substituents on the left side of Figure 1, the reaction solutions became red almost instantly, and the red color disappeared as the reaction proceeded. Extrapolation to zero time gave the  $\lambda_{\max}$  ( $\epsilon$ ) values shown in the last column of Table III. These are nearly identical with reported values for the similarly substituted triphenylcarbinols<sup>11</sup> and support the conclusion that the corresponding carbonium ions of 9–12 form rapidly and undergo a slow, rate-determining ring closure (step 3). In accord with this interpretation and the expectation that positive charge is more dispersed in the transition state than in the ground state, one finds a rather large positive  $\rho$  value. The far better correlation with  $\sigma^+$  than with  $\sigma$  is to be expected, since the ground state is in fact a carbonium ion. Finally, the large negative activation entropy is consistent with the requirement that the 2-phenyl group and the carbonium carbon atom be rather specifically oriented for the reaction

onsequent restriction in degrees of freedom should be in a large entropy effect.

**Other Tests of the Mechanism.** During any given experiment, acid consumed in step 1 is regenerated in step 3, so that good pseudo-first-order kinetics should be (and were) observed. However a difference effect of acidity on the observed rate constants is noted, depending upon whether step 2 or 3 is rate determining. In the former instance, the rate depends on the concentration of  $\text{ROH}_2^+$  which, in turn, depends on equilibrium 1. An increase in the acidity of the medium should increase the equilibrium concentration of  $\text{ROH}_2^+$  and accordingly increase the rate of cyclodehydration. On the other hand, if step 3 is rate determining, all of the carbinol will be rapidly converted to carbonium ion, and there should be relatively little effect of acidity on the rate.

Accordingly, the cyclodehydration rates of several carbinols which follow each of the Hammett correlations were measured as a function of the per cent acetic acid in the reaction medium, with the results in Table IV. The variation in per cent acid

measured in 80% aqueous acetic acid at 25°, with the indicated percentages of sulfuric acid.

rather limited, in order to keep the rates in a suitable range; it was sufficient, however, to establish the essential correctness of the prediction. Cyclization rates for the carbinols on the right of Figure 1 show a strong dependence on acidity, the rate ratios  $k_{6\%}/k_{4\%}$  and  $k_{5\%}/k_{4\%}$  being  $1.72 \pm 0.08$  and  $2.68 \pm$  respectively. On the other hand, these ratios for carbinols for which step 3 is thought to be rate determining are only  $1.07 \pm 0.02$  and  $1.01$  (only one determination).

An alternative explanation for the increased rates with increased acidity for carbinols on the  $-\rho$  correlation would be that step 1 rather than step 2 is rate determining. Although the protonation of oxygen is usually considered to be exceedingly rapid,<sup>12</sup> there is a remote possibility that the environment around the hydroxyl group in 2-phenyltriarylcarbinols was so sterically crowded with hydrophobic groups that protonation might be slow. This possibility was subjected to experimental test. It is well known that many catalyzed reactions proceed more rapidly in  $\text{D}_2\text{O}$  than in  $\text{H}_2\text{O}$ , and this effect has been used as a criterion for pre-equilibrium protonation.<sup>12,13</sup>

For a discussion, see F. A. Long and M. A. Paul, *Chem. Rev.*, (1957).

For a discussion, see K. Wiberg, *ibid.*, 55, 718 (1955).

Accordingly, the cyclodehydration rates of several carbinols on both sides of Figure 1 were determined in 80%  $\text{CH}_3\text{COOD}-\text{D}_2\text{O}$ , with the results given in Table V. A nearly constant rate enhancement of about 3

\* Rates in deuterated solvent were measured in 80%  $\text{CH}_3\text{COOD}-\text{D}_2\text{O}$  containing 4%  $\text{H}_2\text{SO}_4$ , at 25°. Total deuterium enrichment of acidic hydrogen was 97.3%.

is observed for three carbinols (4, 6, and 8) on the  $-\rho$  correlation line which vary by a factor of over 10 in their absolute cyclodehydration rates. On the other hand, carbinol 9 shows almost no solvent deuterium isotope effect, since step 3 is rate determining.

Carbinol 10, which is at the apex of Figure 1, occupies an ambiguous position. It seems likely that here  $k_2$  and  $k_3$  are of comparable magnitude, with the result that an intermediate solvent deuterium isotope effect is observed. Although the rates for cyclodehydration of 10 as measured by product appearance and by carbonium ion disappearance agree well (Table III), it must be pointed out that this carbinol dehydrates so rapidly that it was impossible to get initial rate readings until reaction was already 45% complete at 25°. Attempts to slow the reaction down by lowering the temperature were frustrated by limited solubility of the product, so it was not possible, as hoped, to observe both the appearance and decay of  $\text{R}^+$ .

In summary, all of the data seem to substantiate schemes 1-3 as the correct cyclodehydration mechanism; step 1 is rapid in all cases, but step 2 or 3 may be rate determining, depending on the substituents.

## Experimental Section<sup>14</sup>

**Preparation of 2-Phenyltriarylcarbinols.** One of three procedures was used, depending on the number and type of substituent. These procedures, designated A, B, and C, will be illustrated with examples, to indicate some of the ways in which the problem of isolating pure carbinols was overcome. The results of all the preparations are summarized in Table VI.

**Procedure A. 3-Methoxy-2'-phenyltriphenylmethanol (5).** To the Grignard reagent prepared from 0.643 g (0.0267 g-atom) of high purity magnesium and 5.0 g (0.0267 mole) of 3-bromoanisole in 90 ml of anhydrous tetrahydrofuran there was added ( $\text{N}_2$  atmosphere) dropwise a solution of 3.0 g (0.0166 mole) of 2-phenylbenzophenone in 50 ml of the same solvent. The solution turned blue immediately, but became yellow after 30-hr reflux. After 48-hr reflux, 100 ml of distilled water was added dropwise. Extraction with ether (three 100-ml portions), drying over  $\text{MgSO}_4$ , and evaporation of the solvent gave 6.1 g of a viscous oil. A sample (3.5 g) of the oil was chromatographed on 100 g of Woelm neutral alumina, activity 1, using 50% carbon tetrachloride-benzene as eluent. The major component (1.1 g, 31.1%) was an oil which showed one spot on tlc plates. Remaining fractions yielded 1.8 g of a complex mixture (tlc). The major product crystallized on standing, and was recrystallized from pentane, mp 104-105.5°. Its nmr spectrum ( $\text{CCl}_4$ ) showed singlets at  $\tau$  7.28 (1 H) and 6.42 (3 H) and a multiplet at  $\tau$  3.50-2.68 (18 H).<sup>15</sup>

(14) Melting points are uncorrected. Analyses were performed by the Spang Microanalytical Laboratory, Ann Arbor, Mich.

(15) Infrared and nmr spectra of all compounds are given in the appendix of the Ph.D. Thesis of E. A. S., Michigan State University, 1965.

<sup>a</sup> Compounds are numbered to correspond to the carbinols from which they were prepared (see Table I). <sup>b</sup> Although precise procedures varied, they can in general be grouped into two categories: A, 0.1–0.5 g of the carbinol was dissolved in 10–15 ml of glacial acetic acid, the solution brought to reflux, and three to five drops of concentrated HCl added; the reaction mixture became colored (yellow to red), then clear. On cooling, and addition of a few drops of water, crystals appeared; B, 0.1–0.3 g of the carbinol was dissolved in 15–20 ml of 80% aqueous acetic acid containing 4% H<sub>2</sub>SO<sub>4</sub>, allowed to stand at room temperature until the red color faded to yellow, warmed to 80°, then cooled, water added, and the crystals were collected. Reaction times are given in parentheses, and followed by the per cent yield. <sup>c</sup> Methanol was the recrystallization solvent in all cases. All products showed a single tlc spot. <sup>d</sup> Upper figures calculated, lower figures found. <sup>e</sup> In mμ; s, shoulder. <sup>f</sup> Calculated for Cl: 18.31. Found: Cl, 18.40. <sup>g</sup> Calculated for Cl: 10.05. Found: Cl, 10.00. <sup>h</sup> Calculated for Cl: 10.05. Found: Cl, 10.13. <sup>i</sup> Prepared according to Clarkson and Gomberg (ref 1).

**Procedure B. 4,4'-Dichloro-2''-phenyltriphenylmethanol (1).** Grignard reagent was prepared from 1.35 g (0.0563 g-atom of high purity magnesium and 13.1 g (0.0563 mole) of 2-bromobiphenyl in 50 ml of anhydrous ether. To the refluxing orange solution was added dropwise a solution of 5.5 g (0.0219 mole) of 4,4'-dichlorobenzophenone (Dow Chemical Co.) in 25 ml of anhydrous benzene and 10 ml of ether. After addition, the mixture was refluxed for 24 hr, then allowed to stand at room temperature for 48 hr. The white precipitated complex was filtered through glass wool and washed with anhydrous ether (two 20-ml portions). The complex and glass wool were stirred with 75 ml of ether and decomposed by dropwise addition of distilled water (20 ml). The ether layer

was separated and dried (MgSO<sub>4</sub>) and the solvent removed on a rotary evaporator. The oily residue, when stirred with 20 ml of pentane, gave 2.48 g (28%) of the desired carbinol, mp 116.5–117.0°. Recrystallization from pentane raised the melting point to 118–118.5°. The mother liquors gave 4.8 g of a complex mixture (tlc) containing some of the desired carbinol. The nmr spectrum of 1 in CCl<sub>4</sub> had a singlet at  $\tau$  7.22 (1 H) and a complex multiplet at  $\tau$  4.42–2.67 (16.9 H).<sup>15</sup>

**Procedure C. 4-Methyl-2''-phenyltriphenylmethanol (8).** *p*-Tolylolithium was prepared (N<sub>2</sub> atmosphere) from 0.40 g (0.057 g-atom) of lithium and 10.0 g (0.0585 mole) of *p*-bromotoluene in 75 ml of anhydrous ether. To the gray solution was added drop-

ures in parentheses are estimated from Arrhenius plots. All values are the average of three or more runs, except those marked with an \*, which are the average of only two runs.

er 15 min a solution of 4.0 g (0.0155 mole) of 2-phenylbenzene in 100 ml of anhydrous ether. The mixture was 1 for 1 hr, then decomposed with 50 ml of water. Separation of the ether layer, drying, and evaporation afforded 6.0 g yellow oil which was chromatographed on silica gel (Baker's)  $\text{Cl}_4$  as eluent. The first three fractions (150 ml) yielded 3.0 g pure alcohol; the remaining fractions (350 ml) gave 2.5 g dark oil which became a glass when final traces of solvent were removed. The glass resisted crystallization from pentane or benzene, but on standing for 2 months deposited a few crystals (mp 60–75°) which were used to seed a hexane solution of the oil. In this way, 2.0 g (37%) of 8, recrystallized from hexane, 5–74.5°, were obtained. The product gave a single tlc spot, 80  $\mu$  ( $\epsilon$  790), and an nmr spectrum with singlets at  $\tau$  7.35 and 7.70 (3 H) and a multiplet at  $\tau$  3.38–2.66 (18 H).<sup>14</sup>

**Preparation of 9,9-Diarylfuorenes.** Preparation of these compounds in pure form offered no difficulties, and the procedures described briefly in footnote b of Table VII should suffice for duplicate results.

**Reaction Procedure.** Reactions were carried out in 1-cm, 3-ml, red, rectangular, silica cells in the thermostated cell compartment of a Beckman DB spectrophotometer, using a Tecam circulator unit to control the temperature to  $\pm 0.1^\circ$ . Most reactions were run in a solvent containing  $4.000 \pm 0.001\%$  by weight sulfuric acid in 80% aqueous acetic acid. The solvent was prepared by weighing analytical balance by placing 5 g of  $100 \pm 0.1\%$  sulfuric acid in a stoppered weighing flask and diluting with 80.0% by weight aqueous acetic acid until the desired percentage was obtained.

This volume of solvent was usually sufficient to run the reactions of all the compounds at a single temperature. To minimize the effect of deterioration of the acid solution<sup>15</sup> the solvent was replaced within 5 days.

Solutions of the carbinols were prepared in 5-ml volumetric flasks using anhydrous benzene as the solvent. Aliquots (5  $\mu$ l) of solutions (using a 10- $\mu$ l Hamilton syringe for measurement) were placed in 2-ml volumetric flasks and thermostated until use. Diluted to 2 ml with solvent, the solutions were about  $9 \times 10^{-4}$  M carbinol.

A solution of each 9,9-diarylfuorene was prepared by diluting 5  $\mu$ l of a benzene stock solution of the hydrocarbon with the reaction solvent. This solution was then used to set the exact  $\lambda_{\text{max}}$  wavelength position of the "308-m $\mu$ " band on the instrument wavelength selector.

Aliquots of stock carbinol solution were diluted with thermostated sulfuric acid–acetic acid solution, mixed by six inversions, and poured into the thermostated silica cells, and the recorder was started. Elapsed time was 30 sec at most; time of mixing was taken as zero reaction time. The recorder was then allowed to record the appearance of product as a function of time, measured to an accuracy of 1 sec/hr.

Rate constants were obtained from the expression  $kt = 2.303 \log [A_b^\infty / (A_b^\infty - A_b)]$  where  $A_b$  is the absorbance of the hydrocarbon at time  $t$  and  $A_b^\infty$  is its absorbance at infinite time. For those reactions in which carbonium ion was observable (9–12) the expression was modified to  $kt = 2.303 \log [C_4^\infty(\epsilon_b - \epsilon_d) / (A_b^\infty - A_b)]$  where  $C_4^\infty$  was the initial concentration of carbonium ion,  $\epsilon_b$  and  $\epsilon_d$  were the molar extinction coefficients of the product and the carbonium ion at 308  $\mu$ , and other terms are as defined above, to correct for the finite absorbance of the carbonium ion at "308  $\mu$ ." The rates were also followed, in these cases, by the decrease in absorbance at the  $\lambda_{\text{max}}$  of the carbonium ion (Table III). Plots of  $\log [1 / (A_b^\infty - A_b)]$  were linear in all cases. Rate constants were checked with solvent and stock solutions prepared at different times, and gave excellent agreement. The data are summarized in Tables VIII, IV, and V.

**Preparation of the Deuterated Solvent.** For the results described in Table V, solvent was prepared as follows: to 16.1908 g (0.3202 mole) of  $\text{D}_2\text{O}$  (Merck, Canada) was added dropwise 2.0367 g of  $100 \pm 0.1\%$   $\text{H}_2\text{SO}_4$ . The flask was fitted with a condenser, and 32.6937 g of acetic anhydride was added dropwise. Initial additions caused warming and slight sputtering at the surface. After complete addition, the system was closed and mixed well, then allowed to remain at 25° for 20 hr before use. The final percentage was 4.00%  $\text{H}_2\text{SO}_4$  in 80.0% DOAc and 20.0%  $\text{D}_2\text{O}$ .

**Acknowledgment.** We are indebted to the Army Research Office (Durham) for generous support of this research (DA-31-124-ARO(D)-157).

# Carbanions. X. The Preferential Migration of *p*-Biphenyl in 2-*m*-Biphenyl-2,2-bis(*p*-biphenyl)ethylolithium<sup>1,2</sup>

Erling Grovenstein, Jr., and Gary Wentworth

Contribution from the School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332. Received January 3, 1967

**Abstract:** Reaction of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with lithium in tetrahydrofuran at  $-65^\circ$  yields 2-*m*-biphenyl-2,2-bis(*p*-biphenyl)ethylolithium as shown by carbonation to give 3-*m*-biphenyl-3,3-bis(*p*-biphenyl)propanoic acid. When the solution of 2-*m*-biphenyl-2,2-bis(*p*-biphenyl)ethylolithium is warmed to  $0^\circ$  and held at this temperature 3 hr before carbonation, the crude acid obtained consists of at least  $98.6 \pm 0.4\%$  of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid. The much higher migratory aptitude of *p*-biphenyl than of *m*-biphenyl is taken to indicate that migration of an aryl group in such organolithium compounds occurs in a carbanion by way of a cyclic or bridged transition state or intermediate such as I. Analogies are pointed out to certain related rearrangements involving 1,2 shifts of vinyl, carbonyl, and trimethylsilyl groups, and it is suggested that the area of carbanion rearrangements is more general than usually supposed.

In a previous paper<sup>3</sup> it was shown that 2,2,2-triphenylethylolithium in tetrahydrofuran solution undergoes rearrangement to 1,1,2-triphenylethylolithium in the presence of benzylolithium or phenyllithium- $C^{14}$  without detectable incorporation of benzyl or radioactive phenyl groups. These experiments demonstrate that the 1,2 shift of phenyl occurs without the formation and readdition of kinetically free phenyl radical, phenyl anion, or phenyllithium.<sup>4</sup> The rearrangement was thereby concluded to occur by an intramolecular process. These experiments, however, did not eliminate the possibility<sup>5</sup> that 2,2,2-triphenylethylolithium undergoes elimination of phenyl anion (or radical) but that phenyl anion (or radical) and 1,1-diphenylethene (or corresponding radical anion) exist in a solvent "cage" and recombine before radioactive phenyllithium or benzylolithium can diffuse into the "cage." The possibility that ordinary phenyllithium and 1,1-diphenylethene could exist in such a solvent "cage" and combine before radioactive phenyllithium or benzylolithium could diffuse into the "cage" can be dismissed since phenyllithium was found<sup>3</sup> to add to 1,1-diphenylethene only slowly under the reaction conditions. An attractive variation<sup>6</sup> of the cage-recombination mechanism is that rearrangement of 2,2,2-triphenylethylolithium occurs with elimination of phenyllithium as an ion pair to which 1,1-diphenylethene is bound as a ligand of the lithium ion; the ion pair-olefin complex then collapses to final product before an external organolithium compound can attack the 1,1-diphenylethene in the complex (eq 1).

While such elimination-readdition mechanisms may appear attractive in light of the proof<sup>3,5</sup> of occurrence of an intermolecular elimination-readdition mecha-

nism for rearrangement of 2,2,3-triphenylpropyllithium, in earlier work it was proposed that phenyl migration<sup>7</sup> proceeded by way of a cyclic transition state or reaction intermediate such as I for rearrangement of 2,2,2-triphenylethylolithium; similar transition states

of intermediates were proposed by Zimmerman and Zweig<sup>8</sup> for migration of phenyl in 2,2-diphenylpropyllithium and phenyl or *p*-tolyl in 2-phenyl-2-(*p*-tolyl)propyllithium.

The present investigation was undertaken in order to try to distinguish between the proposed intramolecular elimination-readdition mechanisms of phenyl migration and the intramolecular cyclic mechanism of migration by way of an intermediate or transition state such as I. Such a distinction appears possible since in the elimination-readdition process the unshared electron pair in the phenyl anion or the unpaired electron in the phenyl radical is in an  $sp^2$  orbital which is orthogonal to the aromatic  $\pi$  orbitals of the migrating phenyl group; hence the presence of a substituent at the *meta* or *para* position of the phenyl group would not be expected to greatly affect the rate of elimination of that group as an anion or radical. For comparison, Streitwieser and Lawler<sup>9</sup> have found that the rate of deuterium exchange in biphenyl with lithium cyclohexylamide in cyclohexylamine is for a *para* position only 2.3 times that of a single position in benzene and for a *meta* position 3.7 times that of a position in benzene; similar partial rate factors were reported by Shatenshtein<sup>10</sup> for exchange with potassium amide in

(4) By "kinetically free" we mean that the phenyl radical, phenyl anion, or phenyllithium had sufficient lifetime to diffuse into the surrounding solvent away from the 1,1-diphenylethene (or 1,1-diphenylethene radical anion). It is assumed here that kinetically free phenyl radicals (or anions) would undergo very rapid lithium atom (or lithium cation) transfer reactions with benzylolithium or phenyllithium- $C^{14}$ .

ammonia. For rearrangement of a 2,2,2-triaryllithium proceeding by elimination of an aryl (cf. eq 1), a *m*-biphenyl anion would be expected eliminated somewhat more readily than a *p*-nyl anion and thus *m*-biphenyl should migrate what more readily than *p*-biphenyl.

the other hand if rearrangement of 2,2,2-triarylithium proceeds by way of an intermediate such a *p*-biphenyl group should migrate more readily a *m*-biphenyl group because the intermediate *m* *p*-biphenyl migration should have greater e delocalization than that of III from *m*-biphenyl

tion since the mesomeric effect of the substituent /l group is not conveyed nearly as effectively from a as from a *para* position. In a system of somewhat r electrical demand, *m*- and *p*-phenyl as substituent s increase the ionization constant of phenol<sup>11</sup> ding to the usual linear Hammett relationship if ituent constants of +0.124 and +0.205, respec-, are assigned<sup>12</sup> these groups.

cordingly 2-*m*-biphenyl-2,2-bis(*p*-biphenyl)ethyl-m was prepared by reaction of 2-chloro-1-*m*-nyl-1,1-bis(*p*-biphenyl)ethane with lithium, and relative migratory aptitude of *m*-biphenyl *vs*. enyl was determined.

ts

**Synthesis of 2-Chloro-1-*m*-biphenyl-1,1-bis(*p*-bi-lyl)ethane.** Initially it was intended to prepare compound from chloro-*m*-biphenylbis(*p*-bi-lyl)methane according to the procedure used for ration<sup>13</sup> of 2-chloro-1,1,1-triphenylethane from triphenylmethane. *m*-Biphenylbis(*p*-biphenyl)binol was prepared by reaction of 3-lithiobiphenyl 4,4'-diphenylbenzophenone in tetrahydrofuran; ver attempts to convert this carbinol to the chlo- reaction with acetyl chloride according to the dure<sup>14</sup> for conversion of triphenylcarbinol to triphenylmethane gave a halogen-free product. e reaction of the carbinol with thionyl chloride and ine<sup>15</sup> gave a chlorine-containing product, the ial in our hands proved difficult to purity. Ac- ngly the procedure in Scheme I was adopted. luction of 4,4'-diphenylbenzophenone by the ied Wolff-Kishner procedure of Huang-Minlon<sup>16</sup> an almost quantitative yield of bis(*p*-biphenyl)- ne, whereas Clemmenson reduction under either cidic or alkaline conditions of Martin<sup>17</sup> resulted

F. Kieffer and P. Rumpf, *Compt. Rend.*, **238**, 360 (1954). #### Scheme I

in almost quantitative recovery of unreacted ketone (possibly because of the very low solubility of the ketone in aqueous media). Bromobis(*p*-biphenyl)methane was prepared by reaction of bis(*p*-biphenyl)methane with N-bromosuccinimide according to a general procedure of Zervas and Dilaris<sup>18</sup> except that benzoyl peroxide was employed as catalyst. A preliminary attempt to couple bromobis(*p*-biphenyl)methane with 3-lithiobiphenyl in tetrahydrofuran solution resulted in a 74% yield of 1,1,2,2-tetrakis(*p*-biphenyl)ethane, possibly by way of a halogen-metal interchange.<sup>19</sup> The reaction of bromobis(*p*-biphenyl)methane with 3-*m*-biphenylmagnesium bromide in tetrahydrofuran also gave 1,1,2,2-tetrakis(*p*-biphenyl)ethane in some 84% yield. While halogen-metal interchange in reactions of Grignard reagents has been reported<sup>20</sup> to be more facile in tetrahydrofuran than in ethyl ether, the high yield of symmetrical coupling product under the present conditions is unusual. When the coupling of bromobis(*p*-biphenyl)methane with 3-*m*-biphenylmagnesium bromide was run in ethyl ether, the desired *m*-biphenylbis(*p*-biphenyl)methane was obtained; the best yield of this compound (some 72%) was obtained in ethyl ether-benzene solution<sup>21</sup> along with 18% yield of 1,1,2,2-tetrakis(*p*-biphenyl)ethane. Reaction of *m*-biphenylbis(*p*-biphenyl)methane with potassium amide in ammonia-ether solution gave a deeply colored solution of the corresponding triarylmethylpotassium which reacted readily with an excess of methylene chloride to give 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane. The over-all yield of this chloride from 4,4'-diphenylbenzophenone was about 43%.

**Synthesis of Carboxylic Acids.** In order to characterize the products of carbonation of the organolithium compounds from 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane, it was necessary to synthesize all of the likely carboxylic acids.

3-*m*-Biphenyl-3,3-bis(*p*-biphenyl)propanoic acid was prepared by reaction of *m*-biphenylbis(*p*-biphenyl)carbinol with malonic acid. This reaction is modeled after the procedure of Hellerman<sup>22</sup> for preparation of 3,3,3-triphenylpropanoic acid from triphenylcarbinol; however in the present case after the reactants were heated at a bath temperature of 220° for 12 hr, the starting carbinol was recovered almost quantitatively. Also heating of the reactants with acetic anhydride according to the modification of Hellerman's procedure

suggested by Gagnon<sup>23</sup> failed to give any of the desired carboxylic acid. Evidently because of the high melting point of *m*-biphenylbis(*p*-biphenyl)carbinol, malonic acid decomposes before an effective melt of the reactants can be obtained even in presence of acetic anhydride (bp 140°); however in the presence of higher boiling *n*-butyric anhydride (bp 198°), 3-*m*-biphenyl-1,3-bis(*p*-biphenyl)propanoic acid was obtained though in only 17% yield.

3-*m*-Biphenyl-1,2-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> was synthesized according to the method of Scheme II. Reaction of bromobis(*p*-biphenyl)-

Scheme II

methane with cuprous cyanide at 160° gave the expected nitrile; however attempts to obtain this nitrile by reaction of the same bromide with sodium cyanide in acetone or in dimethyl sulfoxide<sup>24</sup> were unsuccessful. In the latter solvent, after addition of water 4,4'-diphenylbenzophenone (27% yield) was isolated in addition to bis(*p*-biphenyl)carbinol. The carbinol doubtlessly arose from hydrolysis of the bromide while the ketone possibly arose from O-alkylation of the solvent, followed by base-catalyzed elimination. Attempts to hydrolyze bis(*p*-biphenyl)ethanenitrile with dilute potassium hydroxide<sup>25</sup> in diethylene glycol at 80° resulted in essentially quantitative recovery of starting nitrile, while at 160° a 94% yield of bis(*p*-biphenyl)methane arose, doubtlessly by decarboxylation of the desired acid. At 120° bis(*p*-biphenyl)ethanoic acid was obtained in some 60% yield. Methyl bis(*p*-biphenyl)ethanoate was alkylated with 3-(bromomethyl)biphenyl in moderate yield by a procedure similar to that of Hauser;<sup>26</sup> saponification of the product gave the desired 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> in an over-all yield of some 15% from bromobis(*p*-biphenyl)methane.

2-*m*-Biphenyl-2,3-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> was synthesized according to the method of Scheme III. While all of the products from the reactions shown in Scheme III are new compounds, the reactions are quite similar to those which have been discussed earlier (Schemes I and II).

**Reaction of 2-Chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with Lithium.** The reaction of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with lithium in tetrahydrofuran at -65° followed by carbonation gave a carboxylic acid which was found to be identical with the sample of 3-*m*-biphenyl-3,3-bis(*p*-biphenyl)propanoic acid (mp 226.4–228.1°) whose synthesis is reported above. Thus this reaction with

Scheme III

lithium gave the expected organolithium compound and provides confirmation of the structure of the starting chloride.

In contrast reaction of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with lithium in tetrahydrofuran at 0° gave according to Gilman's double-titration technique<sup>27</sup> a 45% yield of organolithium compound and, after carbonation, a 30% yield of crude acid of mp 208.0–209.5°. This acid was essentially identical with the sample of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> (mp 209.0–210.0°) prepared by Scheme III. According to an isotope-dilution analysis with this radioactive acid, 98.1 ± 0.5% of the crude acid was 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid. From this result it is obvious that a *p*-biphenyl group has undergone a 1,2 shift during the reaction of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with lithium at 0° some time prior to carbonation.

In order to provide more information concerning the nature of this rearrangement, the reaction of the chloride was repeated as before with lithium at -65°. After the usual 3-hr stirring period at this temperature, titration indicated a 39% yield of organolithium compound. The solution was then allowed to warm to 0° and stirred at this temperature for 4 hr before carbonation. The crude acid was obtained in 38% yield and according to isotope-dilution analysis contained 98.6 ± 0.4% of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid. This result together with the first reaction at -65° implies that reaction of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane with lithium in tetrahydrofuran at -65° yields 2-*m*-biphenyl-2,2-bis(*p*-biphenyl)ethylolithium and that upon increase of temperature to 0° this organolithium compound rearranges to 1-*m*-biphenyl-1,2-bis(*p*-biphenyl)ethylolithium. Attempts to analyze the crude reaction product for 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid (the product expected for migration of the *m*-biphenyl group) were unsuccessful; the 98.6 ± 0.4% yield of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid corresponds to the minimum amount of *p*-biphenyl migration in the product acid since the remainder of the crude product may have been an impurity (solvent, stopcock grease, etc.).

ssion

present demonstration that in the rearrangement *n*-biphenyl-2,2-bis(*p*-biphenyl)ethylolithium the phenyl group migrates, after statistical correction equal numbers of biphenyl groups, more than times more readily than the *m*-biphenyl group does strong evidence against rearrangement proceeding by elimination of a biphenyl anion and re-union of this anion to the resulting 1,1-bis(biphenyl)ethene according to any of the detailed paths have been previously discussed. This argument is on the basis that a *m*-biphenyl anion should be eliminated more readily than a *p*-biphenyl anion if it gives with the relative ease of formation<sup>9,10</sup> of *p*-biphenyl anions during base-catalyzed hydrogen exchange upon biphenyl are pertinent and if, as stated, a 1,1-bis(*p*-biphenyl)ethene moiety is somewhat more stable than a 1-*m*-biphenyl-*p*-biphenyl in the transition state for the elimination. With less certainty, the present migratory aptitudes rule out migration by way of a biphenyl radical, 1,1-bis(biphenyl)ethene radical anion. This conclusion is based on the probable argument that the 1,1-biphenyl)ethene radical anion is somewhat more stable (thanks to greater electron delocalization) and therefore more readily formed than 1-*m*-biphenyl-*p*-biphenyl)ethene radical anion and also that *m*-biphenyl radical is likely more readily formed than *p*-biphenyl radical because of greater contribution of the polar structure V in the transition state for migration. Structure V should be more stable when the

being cleaved is *m*-biphenyl rather than *p*-biphenyl because of the greater stability of a *m*-biphenyl anion than *p*-biphenyl anion, which is implied by the greater ease of formation of the former. For rearrangement proceeding by way of cleavage into a biphenyl radical and 1,1-bis(biphenyl)ethene radical anion, we would, therefore, anticipate that *m*-biphenyl radical would cleave and hence appear to migrate more readily than *p*-biphenyl radical, a result contrary to the observed migratory aptitudes.

The observed migratory aptitudes are in good agreement with rearrangement proceeding by way of a cyclic transition state or intermediate such as II or III. The energies of II and III which are of significant energetic difference are contained in structures VI and VII,

actively, which are illustrated for simplicity by the canonical structures. In the simple Hückel molecular orbital approximation, the energies of structures VI and VII are the same as those of structures VIII and IX, respectively. Calculations<sup>28</sup>

A. Streitwieser, Jr., and J. I. Brauman, "Supplemental Tables of Molecular Orbital Calculations," Vol. I, Pergamon Press Inc., New York, N. Y., 1965, pp 92 and 94.

show that VIII is more stable than IX by 0.97  $|\beta|$  unit. While  $|\beta|$  must be regarded as an empirical parameter, a value of 35 kcal/mole has been found<sup>29</sup> for attachment of a proton upon a benzenoid ring to give a cationic  $\sigma$  complex. If this value of  $|\beta|$  is assumed in the present case, the equilibrium ratio of VI to VII (or of II to III after statistical correction for unequal numbers of migrating groups) is calculated to be 525; if  $|\beta|$  is 20 kcal/mole, the calculated ratio is 36. These calculations suffice to show that transition states or intermediates II and III differ sufficiently in energy to account for the observed highly preferential migration of *p*-biphenyl over *m*-biphenyl.

While we believe that the present migratory aptitudes are best accommodated by rearrangement occurring in a carbanion by way of II or III, it might be noted that preferential migration of *p*-biphenyl over *m*-biphenyl would also be expected if the rearrangement occurred in the corresponding free radical through transition states or intermediates differing from II or III by one less electron each. Previously it has been argued that the greater migratory aptitude of benzyl over phenyl in rearrangement of 2,2,3-triphenylpropyllithium provides evidence for rearrangement occurring in a carbanion rather than a free radical.<sup>7</sup> While this general argument still appears correct, the conclusion is restricted to migration of benzyl and is not applicable to migration of phenyl in 2,2,2-triphenylethyllithium since migration of benzyl occurs by an intermolecular process while migration of phenyl occurs by an intramolecular process.<sup>3,5</sup> It has also been argued that rearrangement of phenyl in 2,2-diphenylpropyllithium occurs in a carbanion rather than a free radical, because *inter alia* rearrangement of 2-*p*-tolyl-2-phenylpropyllithium occurs with preferential migration of phenyl over *p*-tolyl;<sup>8</sup> in this argument it was assumed on general grounds that *p*-tolyl would migrate more readily than phenyl for rearrangement of a free radical. More recently, however, it has been demonstrated that phenyl migrates more readily than *p*-tolyl in rearrangement of free radicals.<sup>30</sup> While for 1,2 shifts of phenyl and other aryl groups occurring during rearrangements of organolithium compounds, the evidence in favor of rearrangement occurring in a carbanion rather than a free radical is not as strong as once supposed; the general evidence<sup>8,31</sup> can still be most simply accommodated on the view that these are rearrangements of carbanions.

Finally it is of interest to note that intramolecular rearrangements of carbanions or organometallic compounds have been observed for 1,2 shifts of vinyl<sup>32</sup> and carbonyl<sup>33</sup> as well as aryl. These reactions,

stripped of complicating details such as the role of the metallic cation and solvent, can be represented in the simplified form

The remarkable similarity of these three rearrangements does not appear to have received adequate emphasis. While it is not known whether the species (X and XII) shown in brackets are transition states or reaction intermediates, at least cyclopropylcarbinyllithium and magnesium derivatives are stable under certain experimental conditions.<sup>32</sup>

Vinyl, carbonyl, and aryl groups have in common an unsaturated character which permits these groups to accept additional electrons during the course of rearrangement as illustrated by the fairly classical structures of the proposed intermediates (X, XI, XII). It seems reasonable also that groups which are "unsaturated" because of the presence of vacant d or p orbitals on the atom Q to which the carbanionic center becomes attached (see XIII) should have high migratory aptitudes

in carbanion rearrangements.<sup>34</sup> A pertinent example in the field of nitrogen chemistry is provided by the recent report of facile base-catalyzed 1,2 shift of the trimethylsilyl group in various hydrazines;<sup>35</sup> here a vacant 3d orbital of silicon is likely utilized during rearrangement. These considerations imply that the area of carbanion rearrangements is more general than usually supposed and that additional research in this area is desirable. Thus carbanion rearrangements involving a 1,2 shift of an acetylenic group (e.g.,  $\text{C}\equiv\text{CPh}$ ) appear likely. Also numerous possibilities involving hetero atoms (Zn, B, Al, Si, Ge, Sn, P) centrally located in the group Q appear promising. In some of these the intermediate XIII may be isolable; in others polymerization, elimination, or other side reactions may occur in place of rearrangement.

(34) A similar conclusion has been arrived at independently and communicated to us recently by Professor Robert West.

(35) R. West, M. Ishikawa, and R. E. Bailey, *J. Am. Chem. Soc.*, **88**, 4648 (1966); R. E. Bailey and R. West, *ibid.*, **86**, 5369 (1964).

## Experimental Section<sup>36</sup>

**m-Biphenylbis(p-biphenyl)carbinol.** Into a 1000-ml Morton flask equipped with a high-speed stirrer<sup>37</sup> and dropping funnel, 42.0 g (0.180 mole) of 3-bromobiphenyl was added slowly onto 3.33 g (0.480 g-atom) of finely cut lithium and 0.1 ml of methyl iodide in 550 ml of tetrahydrofuran (freshly distilled from  $\text{NaAlH}_4$ ) at 5° under an atmosphere of dry nitrogen. After addition of about one-third of the bromide, the reaction temperature was lowered to -25°, and the remainder of the bromide was added. After addition of the bromide was completed, the deep purple solution was stirred for 1 hr at -25°. Gilman titration<sup>37</sup> indicated the formation of 105 mmoles (58% yield) of 3-lithiotiphenyl. The solution was siphoned through a glass-wool filter (to remove unreacted lithium) under a nitrogen atmosphere into a 3-l. Morton flask. A solution of 30.1 g (0.090 mole) of 4,4'-diphenylbenzophenone<sup>38</sup> in 1500 ml of dry tetrahydrofuran was added at a flask temperature of 5°, over a period of 1 hr, and the resulting green solution was stirred vigorously at room temperature for 1 hr. The reaction mixture was acidified with 400 ml of 5% hydrochloric acid and the tetrahydrofuran removed on a rotating evaporator. The remaining aqueous suspension of solid was extracted with ether. A quantity of off-white solid (7.8 g), which was insoluble in both aqueous and ether phases, was isolated by filtration and dried *in vacuo*. The ether extract upon evaporation to dryness yielded an orange solid residue which was washed with cyclohexane to remove biphenyl. The total weight of crude white and orange product was 20.6 g (mp 201–229°) of a mixture of the desired carbinol and unreacted ketone. Repeated recrystallizations from benzene removed most of the ketone and gave 11.0 g (0.022 mole or 25% yield based on starting ketone) of white powder of mp 227–231°. A 2.00-g sample of this powder was subjected to vacuum sublimation at 230° (0.02 mm), and the sublimate was recrystallized four times from benzene to give 0.83 g of compound, mp 231–233°. This product upon admixture with 4,4'-diphenylbenzophenone (mp 235–237°) had mp 203–222°; moreover the infrared spectrum of the product was substantially different from that of the ketone (O–H absorption at 2.75  $\mu$  and absence of carbonyl absorption at 6.1  $\mu$ ).

*Anal.* Calcd for  $\text{C}_{27}\text{H}_{20}\text{O}$ : C, 90.95; H, 5.78. Found: C, 90.93, 90.90; H, 5.79, 5.88.

Reaction of a portion of the carbinol with acetyl chloride<sup>34</sup> gave, after recrystallization of the product from benzene, a white solid, mp 128–133° dec. A portion of the sample in ethanol failed to give a precipitate when treated with acidified silver nitrate (triphenylmethyl chloride under these conditions gave an instantaneous white precipitate) and the sample also gave a negative sodium fusion test for halogen. The infrared spectrum of the product showed strong absorption at 7.9  $\mu$  (C–O stretching frequency), and the nmr spectrum showed aromatic but no aliphatic hydrogens. The product is likely bis[m-biphenylbis(p-biphenyl)methyl] ether.

**Bis(p-biphenyl)methane.** To a solution of 4,4'-diphenylbenzophenone (75.0 g, 0.224 mole) in 2000 ml of triethylene glycol containing 38 g of potassium hydroxide at 120° was added 44.7 g (0.90 mole) of hydrazine hydrate, and the mixture was heated at gentle reflux (175°) for 3 hr. Excess hydrazine-water was then allowed to distil from the reaction mixture until a flask temperature of 210° was attained and the mixture was maintained at this temperature for 26 hr. The mixture was cooled to room temperature, diluted with an equal volume of water, and filtered. The precipitate was washed well with water and this white solid after drying amounted to 69.8 g (97% yield) of product of mp 157–161°. One recrystallization from absolute ethanol (the product was placed in the cup of a Soxhlet extraction apparatus and extracted with ethanol in order to avoid use of a large quantity of solvent) gave 63.0 g of white crystalline product of mp 162–163° [lit.<sup>39</sup> bis(p-biphenyl)methane

(36) Melting points were taken on a Mel-Temp apparatus and are uncorrected. Nuclear magnetic resonance (nmr) spectra were determined on a Varian Associates A-60 instrument. Infrared spectra were determined on a Perkin-Elmer Infracord Model 137 spectrophotometer. Analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn., and by Bernhardt Microanalytical Laboratory, Mülheim, West Germany. The technique of combustion and counting of radioactive compounds was the same as that described earlier [E. Grovenstein, Jr., S. Chandra, C. E. Collum, and W. E. Davis, Jr., *J. Am. Chem. Soc.*, **88**, 1275 (1966)].

(37) A. A. Morton and L. M. Redman, *Ind. Eng. Chem.*, **40**, 1190 (1948).

(38) C. Calzolari and C. Furlani, *Ann. Triest. Cura Univ. Trieste, Sez. 2*, 22–23, 63 (1953); *Chem. Abstr.*, **49**, 938g (1955).

(39) J. Weiler, *Chem. Ber.*, **7**, 1188 (1874).

2%]. The average yield of crude product from five similar reactions was 96%.

**bis(*p*-biphenyl)methane.** A solution of 11.0 g (0.0343 mole) *p*-biphenyl)methane, 6.71 g (0.0377 mole) of *N*-bromosuccinimide, and 0.05 g of dibenzoyl peroxide in 300 ml of carbon tetrachloride was heated at reflux 76 hr. Three additional 0.05-g portions of dibenzoyl peroxide were added periodically to the reaction mixture. The solution was allowed to cool to room temperature and succinimide was removed by filtration. The filtrate was evaporated to dryness on a rotating evaporator and the light-colored residue, after a recrystallization from benzene-petroleum ether, gave 10.5 g (0.0264 mole, 77% yield) of off-white crystals, mp 138–141°. After further recrystallization from benzene-petroleum ether the product had mp 142–144° [lit.<sup>10</sup> bromobis(*p*-biphenyl)methane mp 143°]. The average yield of six such reactions was 73%.

**1,1,2,2-Tetrakis(*p*-biphenyl)ethane. A. Preparation with 3-biphenyl.** From the reaction of 9.3 g (0.040 mole) of 3-biphenyl with 0.61 g (0.088 g-atom) of lithium in the usual apparatus, a solution of 24 mmoles (60% yield by Gilman method) of 3-lithiobiphenyl in 300 ml of tetrahydrofuran was added at –20°. A solution of 8.0 g (0.020 mole) of bromobis(*p*-biphenyl)methane in 50 ml of tetrahydrofuran was added to the lithium compound at –20° over a period of 20 min. The reaction mixture was stirred for 10 min and then forced onto solid carbon dioxide. To the carbonated mixture was added 200 ml of concentrated hydrochloric acid, and the mixture was extracted with five 10-ml portions of ether. A quantity of solid, which remained undissolved in the ether layers, was isolated by filtration and dried to give 3.96 g of product, mp 260–270°. An additional 0.67 g of crude product [a total of 74% yield of crude 1,1,2,2-tetrakis(*p*-biphenyl)ethane] was isolated from the ether extract together with 1.5 g of 3-biphenylcarboxylic acid and 2.6 g of biphenyl. A portion of the hydrocarbon, mp 260–270°, was heated at 260° (0.5 mm) to remove 0.05 g of volatile impurity. The residue after recrystallizations from chloroform and two recrystallizations from toluene amounted to 0.83 g of white crystals, mp 275–279° [lit.<sup>10</sup> 1,1,2,2-tetrakis(*p*-biphenyl)ethane mp 276–279°].

*Anal.* Calcd for  $C_{26}H_{20}$ : C, 94.00; H, 6.00. Found: C, 93.87; H, 6.17, 5.97.

**B. Preparation with *m*-Biphenylmagnesium Bromide.** A solution of *m*-biphenylmagnesium bromide was prepared by dropwise addition of 13.3 g (0.057 mole) of 3-bromobiphenyl in 50 ml of tetrahydrofuran to 2.53 g (0.104 g-atom) of magnesium turnings in 500 ml of tetrahydrofuran at reflux temperature in the usual Morton apparatus. After 4 hr of vigorous stirring, the reaction mixture was cooled to 25° and a solution of 11.4 g (28.6 mmoles) of bromobis(*p*-biphenyl)methane in 100 ml of tetrahydrofuran was added dropwise over a period of 20 min and stirring was continued for another 20 min before addition of 100 ml of 5% hydrochloric acid. The organic layer was separated, the aqueous layer was extracted with ether, and the ether extract was combined with the organic layer. Evaporation to dryness gave a gummy solid which when washed with chloroform gave 6.2 g of white powder, mp 169–177°. Concentration of the chloroform solution and evaporation of ethanol gave upon chilling 2.0 g of solid which when melted at 245° (0.02 mm) gave 0.38 g of sublimate, mp 192–207°. The residue upon recrystallization from toluene afforded 1.3 g of product, mp 270–276°. The total yield of high-melting product was therefore 7.5 g (83% yield). After recrystallization from toluene the product had mp 274–278°; the infrared absorption spectrum of this product was identical with that of the previous product of 1,1,2,2-tetrakis(*p*-biphenyl)ethane prepared from 3-biphenyl. The sublimate after recrystallization from chloroform-ethanol had mp 205–208° and is likely *m*-biphenylbis(*p*-biphenyl)methane. It was thought possible that the large excess of magnesium used in this reaction might have been responsible for formation of the coupling product of bromobis(*p*-biphenyl)methane. Hence the reaction was repeated but the solution of *m*-biphenylmagnesium bromide was filtered through a glass plug in order to remove unreacted magnesium metal before addition of bromobis(*p*-biphenyl)methane; however, an 84% yield of crude 1,1,2,2-tetrakis(*p*-biphenyl)ethane, mp 271–277°, was obtained.

***p*-Biphenylbis(*p*-biphenyl)methane.** The Grignard reagent bromobiphenyl was prepared in 500 ml of ethyl ether by reaction of 18.6 g (0.080 mole) of 3-bromobiphenyl with 2.04 g (0.084

g-atom) of magnesium turnings at the boiling point of ether with stirring in the usual Morton apparatus for 6 hr. To the solution of *m*-biphenylmagnesium bromide in refluxing ether was added over a 30-min period a slurry of 16.0 g (0.040 mole) of bromobis(*p*-biphenyl)methane in 200 ml of ether, and the mixture was stirred for 30 min before decomposition with 100 ml of 5% hydrochloric acid. A white solid (12.1 g), insoluble in both aqueous and ether phases, was isolated by filtration and had mp 203–227°. The ether phase was condensed to about 150 ml and yielded 2.46 g of white solid, mp 201–229°. The two fractions, after a loss of 4.0 g of the first fraction during an attempt at recrystallization from toluene, were combined and sublimed at a bath temperature of 210–230° (0.03 mm). The sublimate amounted to 8.3 g (44% yield) of product, mp 202–210°. Another vacuum sublimation and two recrystallizations from chloroform-ethanol gave 7.5 g of white solid, mp 205–211°. A chloroform solution of this solid was extracted with several portions of 94% sulfuric acid. The chloroform solution after addition of ethanol and cooling deposited 5.9 g of white solid, mp 211–213°. Vacuum sublimation gave 4.9 g of a white powder, mp 212–213.5°.

*Anal.* Calcd for  $C_{26}H_{20}$ : C, 94.03; H, 5.97; mol wt, 472. Found: C, 93.71, 93.87; H, 6.18, 6.02; mol wt, 508.

A more convenient synthesis of *m*-biphenylbis(*p*-biphenyl)methane utilized benzene to dissolve the bromobis(*p*-biphenyl)methane. From the reaction of 11.65 g (0.050 mole) of 3-bromobiphenyl with 1.22 g (0.050 g-atom) of magnesium turnings, a solution of 0.040 mole (80% yield) of *m*-biphenylmagnesium bromide in 250 ml of ethyl ether was prepared. (The quantitative analysis<sup>11</sup> of the Grignard reagent was carried out by hydrolyzing an aliquot with water, acidifying with dilute sulfuric acid, adjusting the pH to 10 with an ammonium hydroxide-ammonium chloride buffer, and titrating for magnesium ion with a solution of the disodium salt of ethylenediaminetetraacetic acid to an end point marked with Eriochrome Black T. For confirmation a portion of the original acidified hydrolysate was titrated potentiometrically for bromide ion with standardized silver nitrate solution.) A solution of 14.0 g (0.035 mole) of bromobis(*p*-biphenyl)methane in 100 ml of dry benzene was added to the stirred solution of Grignard reagent at room temperature over a period of 30 min, and the resulting mixture was heated at reflux for 1 hr. The reaction mixture was decomposed by addition of 150 ml of 5% hydrochloric acid. A quantity of solid, insoluble in both aqueous and organic phases, was removed by filtration and after drying weighed 14.3 g, mp 193–229°. This material was subjected to vacuum sublimation (0.05 mm); the fraction collected at a bath temperature of 225–240° weighed 11.9 g (72% yield) and had mp 203–208°. The brown residue from the sublimation weighed 2.05 g (18% yield of crude product) and after recrystallization from toluene had mp 272–277°; this material is identified as 1,1,2,2-tetrakis(*p*-biphenyl)ethane and had the same infrared absorption spectrum as the previous more highly purified sample. The ether-benzene phase was evaporated to dryness and the residue extracted with 200 ml of cyclohexane; the undissolved solid consisted of 1.3 g (11% yield) of a substance of mp 147–150°, which was identified as bis(*p*-biphenyl)methanol on the basis of the identity of its infrared absorption spectrum with that of an authentic sample. The 11.9 g of hydrocarbon after another vacuum sublimation and two recrystallizations from chloroform-ethanol gave 8.1 g of white crystals, mp 208–211°. Two further such crystallizations and a final vacuum sublimation gave 5.9 g of product, mp 212–214°, as obtained earlier for *m*-biphenylbis(*p*-biphenyl)methane.

**2-Chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane.** Potassium amide was prepared in a 500-ml Morton flask equipped with a Morton stainless steel, high-speed stirrer and a Dry Ice-acetone condenser, from the reaction of 3.91 g (0.100 g-atom) of potassium with 200 ml of anhydrous ammonia containing a small crystal of ferric nitrate. After the blue color of the solution of potassium metal had changed to gray-brown a slurry of 4.72 g (0.010 mole) of *m*-biphenylbis(*p*-biphenyl)methane in 100 ml of dry ether was added and the resulting mixture stirred vigorously at reflux for 8 hr. The deep purple-blue solution was siphoned under an atmosphere of dry nitrogen into a flask containing 30 ml of freshly distilled methylene chloride at –30°. The blue color disappeared after the mixture was stirred for 15 min. Unreacted potassium amide was destroyed by addition of 5.35 g (0.100 mole) of solid ammonium chloride; then 200 ml of water and 250 ml of methylene chloride was added. The organic phase was separated, dried over

anhydrous magnesium sulfate, and evaporated to dryness on a rotating evaporator. The light tan solid residue was recrystallized from methyl ethyl ketone to give 4.61 g of nearly white powder, mp 219–223° (88.5% yield). This material after five recrystallizations from methyl ethyl ketone gave 3.3 g of white product, mp 223.2–224.3°.

*Anal.* Calcd for  $C_{24}H_{19}Cl$ : C, 87.59; H, 5.61; Cl, 6.80. Found: C, 87.41, 87.35; H, 5.81, 5.67; Cl, 7.10, 6.97.

In a similar preparation an 84% yield of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)methane, mp 218–222°, was obtained.

**3-*m*-Biphenyl-3,3-bis(*p*-biphenyl)propanoic Acid.** In an unsuccessful experiment modeled after the procedure of Hellerman,<sup>22</sup> 2.44 g (5.0 mmoles) of *m*-biphenylbis(*p*-biphenyl)carbinol was ground up in a mortar and pestle with 2.6 g (25 mmoles) of malonic acid and then the mixture was heated at a bath temperature of 225° under a nitrogen atmosphere under conditions such that volatile products could distil from the reaction mixture. Additional 2.6-g portions of malonic acid were added at three 3-hr intervals, and after 12 hr of heating the reaction mixture was ground with an excess of potassium hydroxide and then thoroughly stirred with 500 ml of hot water. Undistilled solid (2.27 g, mp 225–233°) was isolated and identified as unreacted carbinol by its infrared spectrum; acidification of the filtrate failed to yield detectable carboxylic acid. An experiment in which *m*-biphenylbis(*p*-biphenyl)carbinol was heated at reflux with a molecular equivalent of acetic anhydride and 25% excess of malonic acid for 3 hr and then, after removal of acetic anhydride (*in vacuo*), heating was continued at reflux for 6 hr with 1 molar equiv of propionic anhydride, gave an 86% recovery of unreacted carbinol and a dark resin which yielded none of the desired carboxylic acid upon attempted crystallization. In a successful experiment, to an intimate mixture of *m*-biphenylbis(*p*-biphenyl)carbinol (1.00 g, 2.05 mmoles) and malonic acid (2.13 g, 20.5 mmoles) was added 0.35 g (2.2 mmoles) of *n*-butyric anhydride, and the mixture was heated rapidly in an oil bath at 200° until gas evolution had ceased (15 min). After work-up as in the first experiment, 0.73 g of unreacted carbinol was recovered and 0.198 g (16.7% yield) of acid, mp 223–227°. After three recrystallizations from ethanol white crystals, mp 226–228.1°, were obtained.

*Anal.* Calcd for  $C_{39}H_{30}O_2$ : C, 88.27; H, 5.70. Found: C, 88.13, 88.01; H, 5.69, 5.60.

**Bis(*p*-biphenyl)ethanenitrile-1- $C^{14}$ .** In a preliminary experiment a solution of 0.98 g (0.020 mole) of sodium cyanide and 4.0 g (0.010 mole) of bromobis(*p*-biphenyl)methane in 300 ml of dimethyl sulfoxide (Baker Analyzed Reagent) was warmed at about 60° with stirring for 36 hr while protected from atmospheric moisture by a drying tube filled with anhydrous  $CaSO_4$ . The solution was diluted with 800 ml of water and the solid which separated was isolated by filtration. Recrystallization of the solid from ethanol gave 0.90 g (27% yield) of a product, mp 234–236°, which was identified as 4,4'-diphenylbenzophenone according to infrared spectral comparisons. From the mother liquors was isolated 2.4 g (72% yield) of a compound, mp 145–150°, which was primarily bis(*p*-biphenyl)carbinol according to its infrared spectrum.

In another experiment 0.98 g (0.020 mole) of sodium cyanide and 4.0 g (0.010 mole) of bromobis(*p*-biphenyl)methane in 250 ml of acetone (freshly distilled from  $P_2O_5$ ) was heated at reflux with stirring for 72 hr with protection from atmospheric moisture. After dilution with water, only impure bis(*p*-biphenyl)carbinol (2.6 g, 77% yield) was recovered.

In a successful experiment cuprous cyanide- $C^{14}$  was prepared from sodium cyanide- $C^{14}$  (from Tracerlab, Inc.; activity of 9.8  $\mu$ curies/mmmole) according to the procedure<sup>23</sup> for nonradioactive compounds. Freshly dried cuprous cyanide (0.737 g, 8.25 m-equiv) was mixed with 2.98 g (7.48 mmoles) of bromobis(*p*-biphenyl)methane and the mixture heated at 160° under an atmosphere of dry nitrogen for 12 hr. The organic product was extracted from the cooled melt with acetone, the acetone extract evaporated to dryness, and the residue subjected to vacuum sublimation (0.05 mm). The fraction collected at a bath temperature of 150–160° weighed 0.73 g (29% yield) and had mp 146–149°; this was identified as impure bis(*p*-biphenyl)carbinol by its infrared spectrum. The fraction collected at 175–200° weighed 1.83 g (71% yield) and had mp 182–186°. A recrystallization of this material from ethanol gave 1.62 g of white crystals, mp 184–186°. In three such prepara-

tions the average yield of crude bis(*p*-biphenyl)ethanenitrile was 63%. The analytical sample after another recrystallization from ethanol and another vacuum sublimation had mp 185.8–187.2°.

*Anal.* Calcd for  $C_{26}H_{19}N$ : C, 90.40; H, 5.54; N, 4.05. Found: C, 90.42, 90.37; H, 5.74, 5.74; N, 3.75, 3.78.

**Methyl Bis(*p*-biphenyl)ethanoate-1- $C^{14}$ .** In a preliminary experiment bis(*p*-biphenyl)ethanenitrile (0.89 g, 2.6 mmoles) was heated with 125 ml of 0.082 *N* KOH in diethylene glycol at 80° for 10 hr; however, upon cooling to room temperature and dilution with water, the starting nitrile was precipitated (99% recovery). When this experiment was identically repeated except that the temperature was 160° for 8 hr, dilution with water gave 0.77 g (94% yield) of a compound, mp 159–161°, which was identified as bis(*p*-biphenyl)methane by mixture melting point and infrared spectral comparisons. The following procedure was the most successful of a number of others tried for hydrolysis of the nitrile to the corresponding carboxylic acid. A solution of 32 g (0.50 mole) of potassium hydroxide in 100 ml of water was added to a solution of 2.00 g (5.80 mmoles) of bis(*p*-biphenyl)ethanenitrile in 400 ml of diethylene glycol and the resulting solution heated at 120  $\pm$  10° for 48 hr. The solution was cooled to room temperature, diluted with 1.0 l. of water, and filtered to give 0.75 g of precipitate. Vacuum sublimation of this material at a bath temperature of 155–185° (0.05 mm) gave 0.170 g (9.1% yield) of bis(*p*-biphenyl)methane (mp 160–162°) and at 170–190° 0.45 g (22% recovery) of bis(*p*-biphenyl)ethanenitrile. Acidification of the alkaline filtrate with concentrated hydrochloric acid and filtration gave 1.29 g (61% yield) of acid, mp 201–206°. Two recrystallizations from 95% ethanol gave 0.99 g of white crystals, mp 206.5–207.5° [lit.<sup>11</sup> bis(*p*-biphenyl)ethanoic acid mp 208°]. Repetition of this hydrolysis with bis(*p*-biphenyl)ethanenitrile-1- $C^{14}$  gave 60% yield of bis(*p*-biphenyl)ethanoic acid-1- $C^{14}$ . Reaction of an ethereal solution of 0.82 g (2.25 mmoles) of bis(*p*-biphenyl)ethanoic acid-1- $C^{14}$  with an excess of diazomethane in ether at 0° gave, after evaporation of the ether and recrystallization of the residue from methanol, 0.76 g (89% yield) of methyl ester, mp 125–127°. After two further recrystallizations from methanol the product had mp 126.3–127.8°.

*Anal.* Calcd for  $C_{27}H_{22}O_2$ : C, 85.69; H, 5.86. Found: C, 86.00, 85.76; H, 5.67, 5.73.

**3-(Bromoethyl)biphenyl.** A solution of 75.0 g (0.446 mole) of 3-methylbiphenyl (Aldrich Chemical Co.), 87.2 g (0.490 mole) of *N*-bromosuccinimide, and 0.2 g of dibenzoyl peroxide in 400 ml of carbon tetrachloride was heated at reflux. After 3 hr, an additional 0.2 g of dibenzoyl peroxide was added, and then the mixture was heated at reflux for an additional 22 hr. Insoluble succinimide was removed by filtration, solvent was removed on a rotating evaporator, and the residue distilled *in vacuo*. The fraction boiling at 165–180° (1.5 mm) weighed 82.3 g (75% yield) and solidified upon standing. This orange solid, after three recrystallizations from petroleum ether, gave off-white crystals, mp 56.5–58.0°.

*Anal.* Calcd for  $C_{13}H_{11}Br$ : C, 63.18; H, 4.48; Br, 32.34. Found: C, 63.13; 63.33; H, 4.49, 4.55; Br, 32.48, 32.60.

**3-*m*-Biphenyl-2,2-bis(*p*-biphenyl)propanoic Acid-1- $C^{14}$ .** In a 500-ml Morton flask equipped with a stainless-steel Morton high-speed stirrer and Dry Ice-acetone condenser was condensed 200 ml of anhydrous ammonia. Under an atmosphere of dry nitrogen, 0.340 g (8.7 mg-atoms) of potassium and a small crystal of ferric nitrate was added, and the solution stirred for 1 hr. To the resulting solution of potassium amide was added 2.08 g (5.5 mmoles) of methyl bis(*p*-biphenyl)ethanoate-1- $C^{14}$  in 50 ml of anhydrous ether, and the solution stirred for 2 hr. A solution of 1.43 g (5.8 mmoles) of 3-(bromomethyl)biphenyl in 50 ml of anhydrous ether was added over a period of 30 min and the resulting solution stirred for 30 min at reflux. Ammonium chloride (1.0 g) was added, and the ammonia was allowed to evaporate from the mixture. After 100 ml of water was added, the ether phase was separated and allowed to evaporate to dryness. The yellow solid residue was heated at reflux for 15 hr with 250 ml of 15% aqueous potassium hydroxide. A small amount of undissolved, brown solid was removed by filtration and the filtrate acidified with hydrochloric acid. The white solid (2.17 g) which separated from the solution was isolated by filtration and had mp 182–200°. This material was subjected to partial vacuum sublimation at a bath temperature of 200–220° (0.04 mm). The sublimate, after recrystallization from aqueous ethanol, weighed 0.238 g (12% yield) and had mp 205–207°. This substance was identified as bis(*p*-biphenyl)ethanoic

(42) J. V. Supniewski and P. L. Salzberg, "Organic Syntheses," Coll. Vol. I, A. H. Blatt, Ed., John Wiley and Sons, Inc., New York, N. Y., 1948, p. 46.

infrared spectral comparisons. The residue from the sub-  
1, after two recrystallizations from absolute ethanol, gave  
44% yield) of white solid, mp 202–204.5°. After two more  
lizations from ethanol the melting point was 203.5–204.5°.

Calcd for  $C_{23}H_{20}O_2$ : C, 88.27; H, 5.70. Found: C,  
88.34; H, 5.60, 5.68.

**benylcarboxylic Acid.** A solution of *m*-biphenylmagne-  
-omide in 250 ml of ether was prepared by the reaction of 23.3  
) mole) of 3-bromobiphenyl (K and K Laboratories, Inc.)  
55 g (0.105 g-atom) of magnesium turnings. The Grignard  
was siphoned onto a large excess of solid carbon dioxide  
er the usual work-up 10.6 g (53% yield) of acid, mp 160–  
as obtained. After two recrystallizations from ethanol 8.7  
ite crystals was obtained, mp 162–163° (lit.<sup>44</sup> mp 160°).

**Diphenylbenzophenone.** This ketone was synthesized by a  
ire like that used for 4,4'-diphenylbenzophenone.<sup>48</sup> Re-  
-f 18.0 g (0.091 mole) of 3-biphenylcarboxylic acid and 150  
moles) of thionyl chloride at reflux temperature for 2 hr  
-phenylbenzoyl chloride, to which, after removal of excess  
chloride by distillation, was added 250 ml of carbon disul-  
-6 g of anhydrous aluminum chloride, and 28.1 g (0.182 mole)  
enyl. After the initial vigorous reaction had subsided the  
; was heated at reflux with stirring for 3 hr. The black tar-  
duct, after standing overnight, was isolated by filtration,  
with carbon disulfide (to remove unreacted biphenyl), and  
osed with ice-cold concentrated hydrochloric acid. The  
was separated by filtration and washed well with water and  
5% ethanol. The crude product (26.9 g, mp 131–136°)  
crystallization from benzene–petroleum ether amounted to  
66% yield) of white crystals, mp 138–141°. Two recrystal-  
s from ethanol gave 15.5 g of crystals of mp 142–144°. An  
al sample after two further crystallizations from ethanol and  
am sublimation [at a bath temperature of 150° (0.02 mm)]  
143.8–145.0°.

Calcd for  $C_{22}H_{18}O$ : C, 89.79; H, 5.43. Found: C,  
H, 6.05.

**phenyl-*p*-biphenylmethane.** A solution of 14.2 g (0.0425  
if 3,4'-diphenylbenzophenone, 8.5 g (0.17 mole) of hydrazine  
, and 8.4 g (0.128 mole) of potassium hydroxide pellets in 600  
riethylene glycol was heated at 175° for 2 hr. The excess  
ne was allowed to distil from the reaction mixture, where-  
he temperature was raised to 205° and maintained at that  
ature for 36 hr. The solution was cooled to room tem-  
e, diluted with 1500 ml of water, and extracted with six 500-  
ions of ether. The ether extract yielded 13.0 g (95% yield)  
te solid, mp 92–96°. After two recrystallizations from  
l and a distillation in a sublimation apparatus [bath tempera-  
° (0.03 mm)], 9.2 g of hydrocarbon, mp 99.3–100.4°, was ob-

Calcd for  $C_{22}H_{20}$ : C, 93.71; H, 6.29. Found: C,

**so-*m*-biphenyl-*p*-biphenylmethane.** A solution of 9.10  
mmoles) of *m*-biphenyl-*p*-biphenylmethane, 5.35 g (31.3  
s) of *N*-bromosuccinimide, and 0.1 g of dibenzoyl peroxide  
ml of carbon tetrachloride was heated at reflux for 48 hr.  
ditional 0.05 g of dibenzoyl peroxide was added after the  
hr of reaction. Insoluble succinimide, formed in the reac-  
as removed by filtration and the filtrate evaporated to dryness  
ating evaporator. The residue upon recrystallization from  
of cyclohexane gave 3.2 g of yellow powder, mp 142–144°;  
allization of this product gave 2.7 g of nearly white solid, mp  
145°, which was identified as 3,4'-diphenylbenzophenone  
ing to its infrared spectrum. Evaporation of the mother  
from the cyclohexane crystallization gave 6.2 g of nearly  
owder, mp 94–100°; three recrystallizations of this material  
cyclohexane gave 4.9 g of white product, mp 102–103.5°.  
l portion of this product upon two further recrystallizations  
cyclohexane had mp 103.4–104.7°; since the infrared spectrum  
substance showed appreciable contamination with 3,4'-  
ylbenzophenone, the crude bromide was not submitted for  
s but was employed for synthesis of the following acid.

**phenyl-*p*-biphenyl-*p*-biphenylmethane.** A mixture of 4.14  
) mmoles) of crude bromo-*m*-biphenyl-*p*-biphenylmethane  
(102–103.5°) and 1.02 g (11.4 mequiv) of cuprous cyanide-  
radioactivity was 9.8  $\mu$ curies/mmequiv) was heated at 160°  
hr under an atmosphere of dry nitrogen. The organic  
t was extracted from the cooled melt with chloroform, the

chloroform extract evaporated to dryness, and the residue distilled  
in an apparatus for vacuum sublimation at a bath temperature of  
150–195° (0.03 mm). The product amounted to 3.27 g, mp  
135–148°. Recrystallization from ethanol gave 3.0 g of white solid  
of mp 135–148°, whose infrared spectrum indicated that it was a  
mixture of *m*-biphenyl-*p*-biphenylmethanenitrile and 3,4'-di-  
phenylbenzophenone. This mixture was dissolved in 200 ml of  
diethylene glycol and a solution of 16 g (0.25 mole) of potassium  
hydroxide pellets in 50 ml of water was added and the solution  
heated at 110–120° for 24 hr. The solution was diluted with 300  
ml of water and a precipitate (1.26 g) was isolated by filtration of  
the cool solution. This precipitate, mp 137–141°, was identified as  
somewhat impure 3,4'-diphenylbenzophenone according to its infra-  
red spectrum. Acidification of the filtrate with hydrochloric acid  
gave 1.66 g (4.6 mmoles) of acid, mp 168–173°. Two recrystalliza-  
tions from aqueous ethanol gave 1.31 g of white crystals, mp 172–174°.

Anal. Calcd for  $C_{28}H_{20}O_2$ : C, 85.69; H, 5.53. Found: C,

**Methyl *m*-Biphenyl-*p*-biphenylmethanoate-1-C<sup>14</sup>.** An ethereal  
solution of *m*-biphenyl-*p*-biphenylmethanoic acid-1-C<sup>14</sup> (1.03 g,  
2.83 mmoles) was treated at 0° with excess diazomethane. The solu-  
tion was evaporated to dryness and the residue crystallized from  
methanol to give 0.98 g (2.59 mmoles, 91% yield) of ester, mp 87–  
90°. The analytical sample after two further recrystallizations from  
methanol had mp 89.5–90.5°.

Anal. Calcd for  $C_{27}H_{22}O_2$ : C, 85.69; H, 5.86. Found: C,  
85.71, 85.87; H, 5.78, 5.85.

**2-*m*-Biphenyl-2,3-bis(*p*-biphenyl)propanoic Acid-1-C<sup>14</sup>.** 4-  
Methylbiphenyl was synthesized from *p*-toluidine by the procedure  
of Gomberg and Pernert<sup>45</sup> and converted to 4-(bromomethyl)bi-  
phenyl, mp 85–87°, by the method of Zervas and Dilaris<sup>18</sup> (but  
with traces of dibenzoyl peroxide used as catalyst). In a 500-ml  
Morton flask equipped with a stainless steel Morton high-speed  
stirrer and a Dry Ice–acetone condenser, 200 ml of anhydrous  
ammonia was condensed. Potassium (0.415 g, 10.6 mg-atoms)  
and then a small crystal of ferric nitrate were added and the solution  
was stirred for 1 hr (under an atmosphere of dry nitrogen through-  
out this and the following reactions in liquid ammonia solution).  
A solution of 0.950 g (2.51 mmoles) of methyl *m*-biphenyl-*p*-  
biphenylmethanoate-1-C<sup>14</sup> in 75 ml of anhydrous ether was added  
and the resulting solution stirred for 2 hr. A solution of 0.945 g  
(3.8 mmoles) of 4-(bromomethyl)biphenyl in 25 ml of anhydrous  
ether was then added over a period of 10 min and the solution stirred  
for 30 min. Unreacted potassium amide was destroyed by adding  
0.54 g (10 mmoles) of solid ammonium chloride, and the ammonia  
was allowed to evaporate from the mixture. Dilute hydrochloric  
acid was added, the ether phase was separated, and the aqueous  
layer extracted once with ether. Evaporation of the combined  
ether phases yielded a solid residue which was heated at reflux for  
24 hr with 250 ml of 15% aqueous potassium hydroxide. A quan-  
tity of dark brown, undissolved solid was removed by filtration and  
the filtrate acidified with hydrochloric acid. The white solid (0.545  
g, 41% yield) was isolated by filtration and had mp 205–209.5°.  
After four recrystallizations from ethanol, this material yielded  
0.28 g of white crystals, mp 209.0–210.0°.

Anal. Calcd for  $C_{30}H_{20}O_2$ : C, 88.27; H, 5.70. Found: C,  
88.22, 88.39; H, 5.60, 5.58.

**Reaction of 2-Chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane  
with Lithium.** A. Reaction at –65°. To a 500-ml Morton flask  
(previously flame dried under a stream of dry nitrogen) equipped  
with a high-speed stirrer<sup>47</sup> and dropping funnel was added 150 ml  
of tetrahydrofuran (freshly distilled from NaAlH<sub>4</sub>), 0.153 g (22.1  
mg-atoms) of lithium, about 2% of a solution of 3.00 g (5.75  
mmoles) of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane in  
100 ml of dry tetrahydrofuran, and 0.05 ml of methyl iodide. The  
reactants were kept under an atmosphere of dry nitrogen throughout  
all of the following reactions with lithium. The solution was stirred  
vigorously at 0 ± 5° until a faint purple color appeared (2 hr);  
the reaction temperature was then lowered to –65 ± 5° and the  
remainder of the chloride added over a period of 30 min. The  
solution was stirred at –65° for 3 hr; Gilman double titration<sup>47</sup>  
of four 5-ml aliquots of this solution indicated that the yield of  
organolithium compound was 50 ± 10%. The deep purple solu-  
tion was forced onto a large excess of solid carbon dioxide. To the  
carbonated mixture, after sublimation of unreacted carbon dioxide,  
was added 200 ml of 10% sulfuric acid. The acidified mixture was  
extracted with ether and the organic phase was evaporated to dryness.

(45) M. Gomberg and J. C. Pernert, *J. Am. Chem. Soc.*, **48**, 1372  
(1926).

The solid residue was stirred vigorously (3 hr) with 500 ml of 2% aqueous potassium hydroxide. Undissolved solid (2.1 g, mp 190–225°) was separated by filtration. Acidification of the filtrate brought about the precipitation of 0.722 g (24% yield) of solid, mp 225–228°. This acid after three recrystallizations from ethanol amounted to 0.489 g of white crystals, mp 226.5–228°. This acid gave no depression of melting point when mixed with the sample of 3-*m*-biphenyl-3,3-bis(*p*-biphenyl)propanoic acid synthesized above from *m*-biphenylbis(*p*-biphenyl)carbinol. Moreover, the infrared spectra of the acid and the synthetic sample were identical.

**B. Reaction at 0°.** This reaction was run in the same apparatus and by the same general technique as that for the reaction at –65°. To 0.133 g (19.2 mg-atoms) of lithium and 200 ml of tetrahydrofuran was added 0.05 ml of methyl iodide and about 10% of a solution of 2.50 g (4.80 mmoles) of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane in 50 ml of tetrahydrofuran. The solution was stirred vigorously at 0 ± 5° until a purple color appeared (1 hr). Then the remainder of the chloride was added over a period of 30 min at 0° and the solution stirred at this temperature for 6 hr before carbonation. The color of the solution just before carbonation was blue black; Gilman's double titration<sup>27</sup> indicated the presence of 45% yield of organolithium compound. After the usual work-up, 1.88 g of neutral product (mp 109–177°) and 0.995 g (39% yield) of crude acid, mp 208.0–209.5°, were obtained. This acid showed no melting point depression when mixed with a sample of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid synthesized previously according to Scheme III. Mixtures (about 50:50) of the acid with 3-*m*-biphenyl-3,3-bis(*p*-biphenyl)propanoic acid and with 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid (synthesized according to Scheme II) had mp 201–219° and 180–202°, respectively. The infrared spectrum of the acid (in carbon disulfide) was identical with the infrared spectrum of the independently synthesized sample of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid; however, the infrared spectrum of 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid was almost identical with these spectra except that the absorptions at 13.4 and 14.4  $\mu$  were broader.

The remaining crude acid (0.9861 g, mp 208.0–209.5°) was diluted with 0.1386 g of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> (mp 209.0–210.0°, specific activity 9.793 ± 0.002  $\mu$ curies/mole from Scheme III). The mixture was recrystallized to constant specific activity. After four recrystallizations from ethanol and one from benzene, the acid had mp 209.0–210.0° and specific activity 1.227 ± 0.005  $\mu$ curies/mole. From these data, it follows that 98.1 ± 0.5% of the crude acid was 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid.

**C. Reaction at –65° and Rearrangement at 0°.** Reaction between 0.106 g (15.3 mg-atoms) of lithium and 2.00 g (3.84 mmoles) of 2-chloro-1-*m*-biphenyl-1,1-bis(*p*-biphenyl)ethane in 250 ml of tetrahydrofuran at –65 ± 5° was run as in the first run at –65°. After the 3-hr stirring period at this low temperature, Gilman's double titration<sup>27</sup> indicated a 39% yield of organolithium compound. The solution was then allowed to warm to 0 ± 5° and stirred at this temperature for 4 hr before carbonation. After the usual work-up 1.33 g of neutral product (mp 79–132°) and 0.781 g (38% yield) of acid, mp 205–208°, were isolated. This acid gave no depression of melting point and had an infrared spectrum identical with that of a sample of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid (synthesized by Scheme III), while this acid on admixture with the synthetic samples of 3-*m*-biphenyl-3,3-bis(*p*-biphenyl)propanoic acid and with 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid gave mixtures which melted with considerable depression of melting point. The crude acid (0.7802 g), mp 205–208°, was mixed with 0.1400 g of 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup> (activity of 9.793 ± 0.002  $\mu$ curies/mole, mp 209.0–210.0°) and the mixture recrystallized to constant radioactivity. After four recrystallizations from ethanol and two recrystallizations from benzene, the acid had mp 209.2–210.1° and activity of 1.508 ± 0.005  $\mu$ curies/mole. From these data it can be calculated that 98.6 ± 0.4% of the crude acid was 2-*m*-biphenyl-2,3-bis(*p*-biphenyl)propanoic acid.

In an attempt to analyze the crude carboxylic acid from this run and the preceding run at 0° for any 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid, the combined mother liquors from recrystallization of the crude acid from these two runs were evaporated to dryness to give 0.053 g of acid, mp 207–208.5°. To this acid was added 0.50 g of pure 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid-1-C<sup>14</sup>. After one recrystallization from benzene, crystals, mp 175–196°, were obtained; the melting point of this material was not altered after two more recrystallizations from benzene. Benzene was removed from the mother liquors and the residue combined with the recrystallized material. After four recrystallizations from ethanol, crystals, mp 180–197°, were obtained. Since only impure acid was obtained by any of the procedures tried, isotope-dilution analysis for 3-*m*-biphenyl-2,2-bis(*p*-biphenyl)propanoic acid was abandoned.

# Singlet and Triplet Nitrenes. I. Carbethoxynitrene Generated by $\alpha$ Elimination

John S. McConaghy, Jr.,<sup>1</sup> and Walter Lwowski<sup>2</sup>

Contribution from the Department of Chemistry, Yale University, New Haven, Connecticut, and from the Research Center, New Mexico State University, Las Cruces, New Mexico. Received December 10, 1966

**Abstract:** Carbethoxynitrene was generated by  $\alpha$  elimination and the stereospecificity of its addition to *cis*- and *trans*-4-methylpentene-2 was investigated. The addition is the less stereospecific the lower the olefin concentration. The data fit quantitatively a scheme in which all the nitrene is generated in the singlet state, and then decays to triplet in competition with addition to the olefin. Both singlet and triplet add, the former stereospecifically, the latter completely nonstereospecifically. Triplet carbethoxynitrene can be trapped by  $\alpha$ -methylstyrene, with which it reacts at least 85 times faster than with *cis*-4-methylpentene-2. Decay of the singlet nitrene to triplet is about one-thirtieth as fast as addition to the *cis* olefin. The structure of an  $\alpha$ -methylstyrene dimer is revised.

nitrenes<sup>3</sup> have long been discussed as intermediates in organic chemistry,<sup>4,5</sup> and the subject has been well covered.<sup>6-8</sup> For a species  $R-\dot{N}$ ·, singlet and triplet are possible. The singlet with two paired sets of electrons on the nitrogen, or the triplet with one and two electrons of parallel spins, might *a priori* be the ground state of a given nitrene. However, a nitrene need not be generated in its ground state, and it may well react before it reaches the ground state. Beyond ascertaining the nature of the ground state, one has to determine the electronic state of the nitrene in a given chemical reaction before one can give a plausible mechanism for it.

Electron spin resonance studies have shown that the singlet is the ground state for a number of nitrenes,<sup>9-12</sup> including carbethoxynitrene.<sup>13</sup> The ultraviolet spectroscopic triplet nitrenes have also been reported.<sup>14</sup> Little information is available for the electronic state of nitrenes at the moment of their chemical reaction. Attempts have been made to correlate chemical reactivity with electronic multiplicity—radical character ascribed to the triplet species—but such correlations are not unequivocal.

In an attempt to determine the electronic state of carbethoxynitrene at the moment of reaction, we have generated the stereochemistry of the nitrene's addi-

tion to *cis*- and *trans*-4-methylpentene-2. This is an extension into the nitrene field of a method developed by Skell<sup>15</sup> for carbenes. This method, although it caused much controversy,<sup>16</sup> works very well with carbenes. Skell proposed that addition of singlet species to an olefin should produce the three-membered ring adduct in one single step, thus in a stereospecific fashion. A triplet species, however, should first form an open-chain triplet diradical. This is supposed to establish conformational equilibrium, by rotation around the former double bond, much faster than close to the three-membered ring. Skell assumed that the delay in ring closure is due to the necessity of inversion of one of the spins of the triplet diradical. An alternative explanation by Hoffmann<sup>17</sup> does not alter the stereochemical consequences. Written for a nitrene, Skell's scheme is shown in Figure 1.

In the following, we want to show that Skell's scheme explains our data not only qualitatively, but quantitatively as well. Strictly speaking, what we observe is a "stereospecifically adding carbethoxynitrene" and a "nonstereospecifically adding carbethoxynitrene." Our final conclusion is that these can be identified with the singlet and triplet species, respectively. To make the discussion less awkward, we shall call them singlet and triplet from the beginning.

After completion of the work described here, Scheiner<sup>18</sup> presented data which independently support the validity of Skell's scheme, applied to aziridine formation. Scheiner obtained diradical intermediates, of the type shown in Figure 1, not by addition of a nitrene to an olefin, but by direct and by sensitized photodecomposition of triazolines. Direct photolysis gave aziridines stereospecifically, perhaps *via* a singlet diradical, perhaps by a concerted process. Photosensitized decomposition gave aziridines nonstereospecifically, presumably *via* triplet diradical intermediates.

## Results and Discussion

Carbethoxynitrene,  $EtO-CO-N$ , was generated by

The name "nitrene" for species  $R-N$  is most often used, but is controversial. The objection that systematic nomenclature requires ending -ene for unsaturated compounds can perhaps be met by dropping the last "e," and calling the species "nitren." This would be equivalent to the change of "urethane" to "urethan," for the same reason.

Figure 1.

photolysis<sup>19</sup> and thermolysis<sup>19,20</sup> of ethyl azidoformate and by base-induced,  $\alpha$ -elimination of arylsulfonate ion from N-(*p*-nitrobenzenesulfonyloxy) urethan.<sup>21,22</sup> Especially the latter reaction is expected to give initially the singlet carbethoxynitrene, since nonconservation of electron spin seems unlikely in a room-temperature ionic reaction.

Owing to the insolubility of the nitrene precursor I, the  $\alpha$ -elimination method cannot be used in pure hydrocarbons, and a solvent, usually dichloromethane, was employed. Dichloromethane is quite inert toward the nitrene, as shown by the observation<sup>23</sup> that a 35% yield of aziridine was obtained from carbethoxynitrene in a 0.2 mole % solution of cyclohexene in dichloromethane. *cis*- and *trans*-4-methylpentene-2 were employed as the olefins, mostly because they are liquids and are commercially available. As communicated earlier,<sup>24</sup> the degree of stereospecificity of the aziridine formation is strongly dependent on the olefin concentration. Even in pure olefin, the addition is not fully stereospecific. While our work was in progress, Hafner reported<sup>25</sup> that the photolysis of methyl azidoformate in *cis*- and *trans*-2-butene gave 87% *cis*-plus 13% *trans*-aziridines in the former case, and 8% *cis* and 92% *trans* in the latter. During the progress of our work, studies of the dependence of stereospecificity of addition on substrate concentration have been carried out on fluorenylidene,<sup>26</sup> dicyanocarbene,<sup>27</sup> and cyanonitrene.<sup>28</sup>

The imperfect stereospecificity cannot be attributed to secondary reactions. The stability of the star olefins and the products under the reaction conditions was established both by independent experiments by taking samples during early and late stages of individual runs, and comparing the ratios of *cis* and *trans* products. Both olefins and the products were stored under the conditions employed.

Making carbethoxynitrene by  $\alpha$  elimination in chloromethane solutions of *cis*- and *trans*-4-methylpentene-2 gave, as the main products, mixtures of *cis*- and *trans*-1-carbethoxy-2-isopropyl-3-methylaziridine

Table I gives yields and compositions of the aziridine mixtures obtained at olefin concentrations between

Table I. Addition of Carbethoxynitrene to *cis*- and *trans*-4-Methylpentene-2,  $\alpha$ -Elimination Route, Dichloromethane Solutions

Mole % olefin	Yield of aziridines	From <i>cis</i> olefin, % Fraction of <i>trans</i> product	From <i>trans</i> olefin, % Fraction of <i>cis</i> product

proposed Scheme I holds true, the fraction of specific reaction should depend only on the time that elapses from the formation of a nitrone molecule to its consumption. The nitrone should produce only one geometric isomer of aziridine from each (*cis* or *trans*) olefin; the specific triplet reaction should produce the nitrone isomers from either olefin. The fraction of triplet reaction can be calculated from our experimental data if one assumes that the nonstereospecificity is total, i.e., that the composition of the mixture produced by the triplet depends solely on the position of the equilibrium of the two conformers of the open-chain diradical intermediate of Figure 1, on the nature (*cis* or *trans*) of the starting olefin. In the following discussion, we will show that, on the basis of the above assumption, and on Scheme I, the experimental data can indeed be correlated.

In a given experiment, a fraction of the nitrone is produced by the triplet, and will produce (nonstereospecifically) a fraction of the total aziridines obtained. This fraction (different for each substrate concentration) is called *Y*. The aziridine produced by the triplet is a mixture of *trans* and *cis* isomers; the ratio should be constant (see preceding paragraph) and is called *X*. The fraction of *trans*-aziridine in this mixture is called *A*. The values of *X* for each experiment and of *Y* are to be determined from the experimental data: the fractions of *trans*-aziridine in the mixture from *cis* olefin, called *A* (and dependent on olefin concentration), and the fractions of *cis*-aziridine in the aziridine mixtures produced from *trans* olefin, called *B*. *A* and *B* will always be smaller than *X*, since some of the nonstereospecific reaction will produce the same aziridine isomer that is produced specifically by the singlet nitrone. With *Y* being the fraction of triplet reaction, we have

$$A = XY \quad (1)$$

(experiments starting with the *cis* olefin)

$$B = X(1 - Y) \quad (2)$$

(experiments starting with *trans* olefin, the fraction of *cis*-aziridine in the "nonstereospecific mixture" being  $1 - Y$ )

Eq 1 and 2 gives

$$A + B = X \quad (3)$$

Substituting (3) into (1) gives

$$Y = A/(A + B) \quad (4)$$

is supposed to be constant,  $A/(A + B)$  and only  $A/B$  are also supposed to be constant. *A* is obtained from investigation of reactions with *cis* olefin, and *B* from the *trans* olefin. To select values of (concentration-dependent) *A* and *B* a series of *A/B* values and to check for their concentration independence, it is not enough to compare *A* and *B* values obtained at the same concentrations of *cis* and *trans* olefins, respectively. One has to account the different reactivities of the two olefins toward the nitrenes. In our reaction Scheme I, the competition is set up between  $k_2$  and  $k_3[\text{olefin}]$ . For olefins of different reactivity, the latter

term contains different  $k_3$  values, and it becomes necessary to know the ratio of  $k_{3,trans}:k_{3,cis}$ . This ratio was determined by direct competition, using a mixture of 10 mole % *cis*, 20 mole % *trans*-4-methylpentene-2, and 70 mole % dichloromethane. The ratio of reactivities at these particular olefin concentrations was found to be *trans*:*cis* = 0.7. Since the singlet:triplet ratio of carbethoxynitrenes is supposed to change with olefin concentration, one might anticipate that the reactivity ratio would also depend on olefin concentration. Fortunately, there is little or no such dependence. The values for *A* and *B* were plotted vs. olefin concentration, and *A* at a given concentration was compared with the *B* at  $1/0.7$  of that concentration. The values for *A/B* so obtained vary from 3.7 to 4.15 for concentrations from 33 to 1.5 mole %, and no clear trend is observed. Thus, the ratios of reactivities of *cis* and *trans* olefins seem to be nearly the same for the reactions with singlet and triplet carbethoxynitrone. The average of these reactivity-corrected *A/B* values is 3.9; thus *Y* is found to be 0.80 and the fraction of *trans*-oid open-chain diradical intermediate in our case is 80%. *X*, the fraction of triplet reaction, then is calculated as  $A/0.8$  or  $X = 1.25A$ . *X* equals 1.25 times the fraction of *trans*-aziridine in the aziridine mixture produced from *cis* olefin. It may be mentioned here that the average value for *A/B* obtained from experiments with photolytically generated nitrone (100 and 1.5 mole % olefin) is 3.87. The relation  $X = 1.25A$  is sufficiently accurate for our further use, since a 10% error in the ratio *A/B* would lead only to a 3% error in the factor 1.25.

If we use Scheme I, neglect side reactions of the triplet ( $k_3$ ), and call the aziridine from singlet nitrone *S*, the aziridine mixture from the triplet nitrone *T*, the singlet nitrone *N*, the triplet nitrone  $^3N$ , and assume that nitrone production is the slow reaction step, then

$$d[T]/dt = k_4[^3N][\text{olefin}]$$

$$d[S]/dt = k_3[N][\text{olefin}]$$

$$(d[T]/dt)/(d[S]/dt) = k_4[^3N]/k_3[N]$$

and with  $d[^3N]/dt = 0$

$$d[^3N]/dt = k_2[N] - k_4[^3N][\text{olefin}] = 0$$

$$[^3N]/[N] = k_2/k_4[\text{olefin}]$$

and

$$(d[T]/dt)/(d[S]/dt) = k_4k_2/k_3k_4[\text{olefin}] = k_2/k_3[\text{olefin}]$$

with the olefin concentration constant throughout the run

$$[T]/[S] = k_2/k_3[\text{olefin}]$$

Consequently, a plot of  $[T]/[S]$  vs.  $1/[\text{olefin}]$  should give a straight line with the slope  $k_2/k_3$ . Table II gives the data used to construct Figure 2.

The curve in Figure 2 follows the predicted straight line only down to about 3 mole % olefin. In our computation,  $k_3$  was neglected; that is, the assumption was made that all triplet nitrone produced is quantitatively converted to aziridines. At low olefin concentrations, this seems not nearly to be true, and the scheme has to be refined. It is not necessary to take into account side

Figure 2.

reactions of the singlet nitrene, since the steady-state assumption  $d[N]/dt = 0$  was not needed in the calculations made above. However, the assumption  $d[{}^3N]/dt = 0$  was made, and side reactions of the triplet nitrene have to be considered. Adding the reaction

is indeed all that is required to obtain a straight line in Figure 2. The reaction or reactions described by  $k_5$  could be those of the triplet nitrene with solvent. Re-

**Table II.** Addition of Carboethoxynitrene to *cis*-4-Methylpentene-2,  $\alpha$ -Elimination Route, Dichloromethane Solution, Reduced Data

$[Olefin]^{-1}$	$A$	$[T]$	$[S]$	$[T]/[S]$
3	0.078	0.098	0.90	0.11
10	0.175	0.22	0.78	0.28
20	0.26	0.325	0.675	0.48
30	0.34	0.425	0.575	0.74
40	0.375	0.47	0.53	0.89
67	0.43	0.54	0.46	1.18

arrangement or dissociation of the triplet nitrene, as well as return to the singlet state, could also be contained in  $k_5$ . With the new reaction, we have

$$d[{}^3N]/dt = k_2[N] - k_4[{}^3N][olefin] - k_5[{}^3N] = 0$$

In the same way as above, this yields

$$[T]/[S] = k_2 / \{k_3([olefin] + k_5/k_4)\}$$

Thus, a plot of  $[T]/[S]$  vs.  $1/([olefin] + k_5/k_4)$  should now give a straight line. To find  $k_5/k_4$ , the logarithms of all our  $[T]/[S]$  values were plotted against  $\log 1/([olefin] + x)$  and various values tried. With  $x = 0.01$  to  $0.025$ , straight lines could be drawn that passed through the error boxes of all points. The best fit seems to be given by  $k_5/k_4 = 0.015$ . Figure 3 shows plots with  $k_5/k_4$  taken as 0.01, 0.015, and 0.025. The slopes of the lines in Figure 3 correspond to  $k_2/k_3$ , the ratio of the (first-

Figure 3.

order) rate constant of singlet-triplet conversion and the (second-order) rate constant for the singlet addition to *cis*-4-methylpentene-2. If  $k_5/k_4$  is taken to be  $0.015 \pm 0.005$ , the  $k_2/k_3$  is equal to  $0.036 \pm 0.004$ . Thus it appears that the addition of the singlet nitrene is about 30 times as fast as the decay to triplet.

The quantitative compatibility of the observed data with a scheme based on singlet-triplet conversion competing with the addition of singlet to olefin is encouraging, but does not itself prove the validity of the scheme. To provide independent evidence, attempts were made to trap the triplet nitrene selectively.

**Trapping of Triplet Carboethoxynitrene.** The reactions reported above were done in degassed solutions under nitrogen. Changing to solutions saturated with oxygen resulted in slightly more stereospecific addition (at 3.3 mole % olefin concentration), but the change was not large enough to be convincing. Since the first intermediate in the addition of the triplet nitrene to an olefin is supposed to be a diradical, we tried next an addend which would give a highly stabilized diradical, hoping that this stabilization might be reflected in the transition state enough to lead to very fast addition. Our choice was  $\alpha$ -methylstyrene, which we did not expect to be particularly reactive toward the singlet nitrene. Indeed, addition of 3.3 mole % of  $\beta$ -methylstyrene to an otherwise unchanged run with 3.3 mole % *cis*-4-methylpentene-2 in dichloromethane gave a 16% yield of *cis*-1-carboethoxy-2-isopropyl-3-methylaziridine, and only a trace of the *trans* isomer. Without the  $\alpha$ -methylstyrene, the reaction gave a 25% yield of the *cis*- and a 13% yield of the *trans*-aziridine. A similar experiment, using 1.5 mole % each of  $\alpha$ -methylstyrene and *cis*-4-methylpentene-2, gave an aziridine mixture containing at the most 2.1% of the *trans* compound. Thus, the  $\alpha$ -methylstyrene reduced the yield of the *cis*

by a factor of 1.6, but the yield of *trans* product is a factor of greater than 30 (at 3.3 mole % concentration). The simplest explanation is that the triplet is removed because its reaction rate with  $\alpha$ -methylstyrene is much greater than that of the singlet. The rate I is extended by the reaction

$\alpha$  stands for  $\alpha$ -methylstyrene, then a treatment analogous to the one used above gives

$$[T]/[S] = k_2/[k_3([\text{olefin}] + k_5/k_4) + k_a[\alpha]/k_4]$$

Values except  $k_a[\alpha]/k_4$  are known, and  $k_a/k_4$  is estimated to be 86 (using  $A = 0.021$  and  $[T]/[S] =$

It appears that  $\alpha$ -methylstyrene is 86 times more reactive toward triplet carbethoxynitrene than is ethylpentene-2. Since the 2.1% *trans*-aziridine product mixture is the maximum value, the rate for the  $\alpha$ -methylstyrene might be greater. Our results agree very well with Skell's contention that the triplet state in the triplet addition has much radical character. The nature of the product from  $\alpha$ -methylstyrene and carbethoxynitrene supports this further. An aziridine corresponding to nitrene addition to the  $\alpha$ -methylstyrene could not be found. The main product is a 1:1 adduct, 3-carbethoxyamino-2-phenylpentene-1 (VI). Its structure was established by its infrared spectra, elemental analysis, and independent synthesis. Presumably, VI is formed not by insertion into the methyl group, but *via* a di-intermediate.

possibility that VI is a decomposition product of the dimer formed from  $\alpha$ -methylstyrene was not rigorously tested, but it was shown that VI is present in the reaction mixture before the gas chromatographic separation.

**Unsaturated Dimer of  $\alpha$ -Methylstyrene.** Vpc analysis of the product mixture from  $\alpha$ -methylstyrene and carbethoxynitrene (produced by  $\alpha$  elimination) showed a further major product, which was found to be present as well as in the absence of *cis*-4-methylpentene-2 in the reaction mixture. The new product was found to be identical with the "liquid dimer" or "unsaturated dimer" of  $\alpha$ -methylstyrene. This dimer had been characterized by Bergmann<sup>29</sup> and later by Hukki,<sup>30</sup> and had been assigned the structure of 2,4-diphenyl-4-pentene-2 on the basis of ozonization studies.<sup>29</sup> We observed 2,4-ditoyl-4-methylpentene-1 among the products of the (analogous) acid-induced dimerization of dimethylstyrene, and proposed that the corresponding terminal olefin also might be present in the product from acid-induced dimerization of  $\alpha$ -methyl-

styrene, and that Bergmann might have overlooked it. We prepared the  $\alpha$ -methylstyrene dimer by Hukki's method, and found it to have vpc retention time, infrared, and nmr spectra identical with the product from the reaction of our nitrene with  $\alpha$ -methylstyrene in dichloromethane. The vpc analysis shows that little or no isomeric olefin is present, and the nmr spectrum shows two nonequivalent vinyl protons. This, and the rest of the spectral data, establish the structure of the liquid, unsaturated  $\alpha$ -methylstyrene dimer as 2,4-diphenyl-4-methylpentene-1.

A broad multiplet representing the ten aromatic protons is centered around  $\delta 7.1$ .

As shown by a control experiment, the strongest acid present in our system, triethylammonium ion, does not convert  $\alpha$ -methylstyrene to the dimer. In our case, it is probably formed by a radical chain mechanism, such as

**Side Reactions of Carbethoxynitrene.** In the preceding discussion, only aziridines were considered as products from nitrene and the 4-methylpentene-2. The experience gathered with other olefins<sup>19,22</sup> leads one to expect other products as well: all the possible insertion products, especially the allylic ones. A crude estimation, based on the data from cyclohexene experiments, shows that only the insertion product into the tertiary C-H bond at C-4 is expected to be formed in a quantity greater than 1% of the quantity of the aziridines. However, the 4-carbethoxyamino-4-methylpentene-2 might be formed in a quantity as much as 12% of that of the aziridines. While C-H insertion seems to be a property of the singlet only,<sup>23</sup> and thus should not influence the stereospecificity (see above), it was at first surprising that no tertiary allylic insertion product could be found. Inspection of models, however, shows that the tertiary allylic hydrogen in *cis*-4-methylpentene-2 is very shielded by three methyl groups, and attack on the C-4-H bond would be very difficult sterically. In the *trans* olefin, the steric hindrance of such an attack is also severe.

While C-H insertion seems to make a negligible contribution, a more serious interference could be caused

<sup>29</sup> Bergmann, H. Taubadel, and H. Weiss, *Ber.*, **64B**, 1493 (1931).  
<sup>30</sup> Hukki, *Acta Chem. Scand.*, **3**, 279 (1949).

by reactions of the triplet nitrene with olefin other than aziridine formation. Especially formation of 4-carbethoxyamino-2-methylpentene-2 (VIII) was anticipated.

Compound VIII was synthesized and a reaction mixture that contained a high proportion of triplet products (from a run with 1.5 mole % olefin concentration) was analyzed for VIII. A trace of a product with vpc retention time identical with that of VIII was found, but its quantity was too small to attempt identification by infrared spectrum. The peak area corresponded to its being formed in a yield no greater than 2.4% of the aziridine yield, or no greater than 4.5% of the yield of the part of the aziridines formed from the triplet nitrene. Consequently this side reaction does not seriously affect our conclusions.

## Conclusion

The results discussed above show that the  $\alpha$ -elimination route produces carbethoxynitrene that adds fully stereospecifically to the methylpentenes (extrapolation to infinite olefin concentration), but changes to a nitrene that adds nonstereospecifically. Since the mode of generation makes it very likely that the singlet nitrene is produced, and since the ground state has been proved to be the triplet,<sup>13</sup> we think it reasonable to identify the two species with the singlet and the triplet states. Our results with  $\alpha$ -methylstyrene support the contention that the intermediate produced in the nonstereospecific process is a diradical.

## Experimental Section

**General.** Infrared spectra were obtained with a Perkin-Elmer Model 421 spectrometer. Unless specified otherwise, carbon tetrachloride was the solvent used for the infrared as well as the proton magnetic resonance spectra. Tetramethylsilane was used as an internal standard for the latter, and the chemical shifts are reported as  $\delta$  values (ppm downfield from the TMS signal). Ultraviolet spectra were taken on a Cary Model 14 spectrometer, mass spectra on a Model 21-103 Consolidated Electrodynamics Corp. instrument.<sup>31</sup> Microanalyses are by Galbraith Laboratories. Melting points were taken on a Fisher-Jones block, and are uncorrected, as are the boiling points. Vapor phase chromatography was done with a Varian Aerograph Model A-90-P unit and helium was used as the carrier gas. The columns employed were: column A: 6 ft  $\times$  0.25 in. stainless steel; 20% GE-SF-96 silicone oil on 60-80 mesh Firebrick; column B: 15 ft  $\times$  0.25 in. aluminum; 5% cyanosili-

cone XF 1150 on 45-60 mesh Chromosorb W; column C: 15 ft  $\times$  0.25 in. aluminum; 20% Carbowax 20M on 45-60 mesh Chromosorb W; and column F: 11 ft  $\times$  0.25 in. stainless steel; 25% silver nitrate in glycerol on 60-80 mesh Chromosorb P.

Quantitative vpc analyses were carried out by making four injections per determination, tracing the peaks on unlined filing cards, cutting them out, and weighing. The error was taken to be twice the standard deviation found. Relative errors were less than 2% where the ratio of compared peak areas was less than 10:1. To obtain absolute yields, the peaks from aliquots of reaction mixtures were compared with peaks from the injections of known volumes of standard solutions of the product in question. Unless stated otherwise, all reactions were run under nitrogen, and the solvents were deoxygenated before use. *cis*- and *trans*-4-methylpentene-2 were Phillips "pure grade," 99+ % pure. The olefins were distilled before use and gave a negative peroxide test. Each sample of olefin was first analyzed by gas chromatography on column F. If a measurable amount of the other isomer was found, it was corrected for, but such corrections never were larger than 1%. Triethylamine (Matheson Coleman and Bell) was distilled from barium oxide. Dichloromethane (Fisher Certified Reagent) was used without further purification.

**Preparation of Authentic *cis*- and *trans*-1-Carbethoxy-2-isopropyl-3-methylaziridines (IV and V).** The aziridines were prepared by a slight modification of Hassner's method.<sup>32</sup>

**a. N-Carbethoxy-2-amino-3-iodo-4-methylpentanes.** Iodine (25.4 g, 0.1 mole) was added in one portion to a stirred, cooled mixture of 20 g (0.133 mole) of freshly prepared, dry, silver cyanate, 8.4 g (0.1 mole) of *cis*- or *trans*-4-methylpentene-2, and 200 ml of anhydrous ether. After 2 hr of stirring in an ice-salt bath and 1 hr at room temperature, the filtered solution was concentrated to half its original volume, 200 ml of absolute ethanol was added, and the solution heated to reflux for 2 hr. Solvent was distilled to reduce the volume by half, and the solution was poured into 150 ml of water, containing a little sodium sulfite. The aqueous layer was washed once with ether, and the combined organic layers were washed five times with water. The combined aqueous extracts were once extracted with ether, and this ether extract was washed five times with water. The washed ether extract was combined with the other organic phase, washed once with saturated sodium chloride solution, and dried over sodium sulfate. Evaporating the ether left the products as yellow oils. The crude yield from the *cis* olefin was 23.3 g (78%), from the *trans* olefin 20.8 g (70%). Both iodo urethans show the ester carbonyl band at 1720  $\text{cm}^{-1}$ ; the NH band of the compound from *cis* olefin is at 3435, that from the *trans* olefin is at 3440  $\text{cm}^{-1}$ . The nmr spectra of the products from *cis* and *trans* olefin are different in that the isopropyl  $\text{CH}_3$  signals form two doublets at  $\delta$  1.01 and 1.07 in the product from *trans* olefin, while they are not separated (at  $\delta$  1.00) in the product from *cis* olefin. The other nmr signal positions are common to both products:  $\text{CH}_3$  at C-1 at  $\delta$  1.12, ethoxy  $\text{CH}_3$  at 1.12, isopropyl CH at 1.3-1.8, N-C-H at 3.3-3.7, I-C-H at 3.8-4.1, ethoxy  $\text{CH}_2$  at 4.04, and N-H at 5.25. The products crystallized on standing in the refrigerator, but were usually used as oils without further purification.

**b. 1-Carbethoxy-2-isopropyl-3-methylaziridines (VI and V).** A solution of the appropriate N-carbethoxy-2-amino-3-iodo-4-methylpentane (15 g, 0.05 mole) in 15 ml of *t*-butyl alcohol was added in one portion to a rapidly stirred solution of 15 g (0.134 mole) of potassium *t*-butoxide (MSA Research Corp.) in 200 ml of *t*-butyl alcohol. After 10 min of stirring at room temperature, the mixture was poured into a solution of 15 g of ammonium chloride in 400 ml of water. The solution was extracted twice with 200-ml portions of ether, and the ether phase was washed with water and sodium chloride solution and dried. After removal of ether and *t*-butyl alcohol, the product was distilled over a short Vigreux column. The *cis*-aziridine had bp 63-66° (3 mm); the *trans* boiled at 67-70° (3 mm). The yields were 3.38 g (40%) for the *cis*, and 4.42 g (51%) for the *trans* isomer. Vpc analysis on column B showed the products not to be contaminated by the other isomers. Infrared and nmr spectra confirm the structures of IV and V. The signals from the methyl groups are split not only by the H on the adjacent carbon, but also due to the asymmetry on ring carbon 2 ( $J = 12$  cps for the *cis*,  $J = 4$  cps for the *trans*-aziridine). Similar effects have been observed,<sup>33</sup> and it has been suggested that restricted rotation

**Induced Decomposition of N-(*p*-Nitrobenzenesulfonyl)urea in Solutions of 4-Methylpentene-2 and Dichloromethane.** A rapidly stirred solution of 0.252 g (0.00087 mole) of I in 30 ml appropriate dichloromethane-olefin mixture was added dropwise 8 min 0.10 g (0.0010 mole) of triethylamine in 10 ml of the chloromethane-olefin mixture. The temperature was maintained between 35 and 40°. After 3 hr, the volume was reduced to 1 ml, and 50 ml of ether was added to precipitate the triethylammonium *p*-nitrobenzenesulfonate, which was usually obtained in 100% yield. The solvent was removed from the filtrate, and the residue analyzed by vpc. Urethan, IV, and V, were identified by their retention times and their infrared spectra, IV and V also by their infrared spectra. No single column was found to separate all the components. Column A separated urethan and diethyl hydrazodiformate from the aziridines IV and V; column B separated the components from each other, but not V from diethyl hydrazodiformate; column C separated all components but a decomposition product (possibly from the aziridines) appeared together with IV. The standard procedure used was to separate the aziridines from the decomposition products on column A (120°), collect them, and analyze them on column B (112°) to determine their ratio. A synthetic mixture of IV and V was analyzed on column B directly, and after passing it through column A, the fraction of IV was found to be 45.1%, respectively, showing that passage over column A did not affect the ratio of IV:V. Aziridine mixtures containing small quantities of urethan were analyzed both directly on column A and after passage over column A. The results confirmed the validity of the method. Analysis of recovered olefin on column F showed that less than 1% had isomerized. To determine the influence of the ratio of nitrene precursor to olefin, the reaction using 1.5 mole % olefin concentration was repeated, at 40 but 400 ml of the dichloromethane-olefin mixtures. Results are shown in Table IV.

**Competition of *cis*- and *trans*-4-Methylpentene-2 for the Nitrene.** Decomposition of I as above in solvent consisting of 10 mole % of *cis* and 20 mole % of *trans* olefin, and 70 mole % of dichloromethane, and work-up as above, gave IV and V in the ratio 1:1.73. The relative reactivity was calculated assuming that the nitrene would react with the *cis* olefin with the same stereospecificity as in a solution containing 10 mole % *cis* olefin, 90 mole % dichloromethane [V:(IV + V) = 0.175], and with the *trans* olefin as if in a solution of 20 mole % *trans* olefin and 80 mole % dichloromethane [IV:(IV + V) = 0.04]. Under these assumptions, the reactivity of the *trans* olefin is calculated to 0.70 times that of the *cis* olefin.

**Preparation of 3-Carboethoxamino-2-phenylpropene-1. a. Bromination of  $\alpha$ -methylstyrene.** A mixture of about 75% 3-bromo-2-phenylpropene-1 and 25% 1-bromo-2-phenylpropene-1 in 52% yield. This mixture, a powerful lachrymator, was used in the next step.

b. To prepare 3-N-phthalimido-2-phenylpropene-1, 5.07 g (0.0257 mole) of the bromophenylpropene mixture was treated with 4.7 g (0.0254 mole) of potassium phthalimide in 20 ml of dimethylformamide at 40°, then 55° for 2 hr. Diluting with chloroform, washing with water and sodium hydroxide solution, drying, and concentrating *in vacuo* gave crystals. Recrystallization from cyclohexane gave product (3.94 g, 58% yield), mp 123-124°.

c. To prepare 3-amino-2-phenylpropene-1, 3.4 g (0.013 mole) of the phthalimido compound was heated to reflux for 1 hr in 30 ml of methanol containing 1.2 ml (0.02 mole) of 85% hydrazine hydrate. After addition of 20 ml of water, just enough hydrochloric acid was added to make the solution acidic. After filtration, the solution was concentrated, 15 ml of 6 N sodium hydroxide solution was added, and the mixture extracted four times with 30-ml portions of ether. From the dried ether extract, 1.03 g (60% yield) of 3-amino-2-phenylpropene-1 was isolated by distillation, bp 95-98° (17 mm). Tiffeneau reported bp 90-92° (14 mm).<sup>36</sup>

d. **3-Carboethoxamino-2-phenylpropene-1.** A solution of 0.85 g (0.0064 mole) of the amine and 0.65 g (0.0064 mole) of triethylamine in 15 ml of ether was treated in an ice bath with 0.70 g (0.0064 mole) of ethyl chloroformate. Filtration and removal of the ether gave a product, bp 123-125° (2 mm), a pale yellow solid, mp 39.5-41.5°, yield 0.82 g (63%). The infrared spectrum showed N-H at 3457 (sharp) and 3360 (broad); olefinic and aromatic C-H at 3090, 3060, and 3030; carbonyl at 1720; C=C at 1628; aromatic ring at 1600 (weak) and 1500 cm<sup>-1</sup>. The nmr spectrum showed the ethoxy CH<sub>3</sub> at  $\delta$  1.22 (t), ethoxy CH<sub>2</sub> at 4.04 (q), CH<sub>2</sub> at 4.15 (d), olefinic C-H's at 5.20 and 5.34, N-H at 5.3-5.8, and the aromatic CH's at 7.34.

Anal. Calcd for C<sub>12</sub>H<sub>13</sub>NO<sub>2</sub>: C, 70.22; H, 7.37; N, 6.83. Found: C, 70.27; H, 7.44; N, 7.01.

The  $\alpha$ -methylstyrene dimer, 2,4-diphenyl-4-methylpentene-1, was prepared after Hukki.<sup>30</sup> Its infrared spectrum showed olefinic and aromatic C-H's at 3087, 3060, 3025; C=C at 1623; aromatic ring at 1600 and 1490 cm<sup>-1</sup>. The nmr spectrum showed the methyl signal at  $\delta$  1.18 (s, 6.0); CH<sub>2</sub> at 2.77 (s, 2.1); olefinic C-H at 4.74 (broad, 1.0) and 5.08 (broad, 0.95); aromatic CH centered around 7.1 (multiplet, area 9.5).

**Reaction of Carboethoxynitrene with  $\alpha$ -Methylstyrene.** A solution of 0.254 g (0.00088 mole) of I in a mixture of 35 ml of dichloromethane and 2.5 ml of  $\alpha$ -methylstyrene (3.5 mole % in  $\alpha$ -methylstyrene) was decomposed and worked up as described above. Vpc analysis on column A (210°) gave two major peaks, identified as 3-carboethoxamino-2-phenylpropene-1 and 2,4-diphenyl-4-methylpentene-1, respectively, by comparison of their vpc retention times and infrared and nmr spectra with those of the authentic compounds.

To determine whether the 3-carboethoxamino-2-phenylpropene-1 was formed during the vpc analysis from some other original reaction product, the original reaction mixture was analyzed by thin layer chromatography, using five solvent systems (cyclohexane:dichloromethane:ethyl acetate, 2:2:1; benzene-ether, 1:1; benzene-ether, 95:5; benzene; and dichloromethane). On silica gel (Merck), in all cases a spot was found that had run as far as a spot of the authentic compound.

**Reaction of Carboethoxynitrene with *cis*-4-Methylpentene and  $\alpha$ -Methylstyrene in Dichloromethane.** The same procedure as described above for solutions not containing  $\alpha$ -methylstyrene was employed. The analysis procedure could be employed unchanged,

(35) H. Pines, H. Alul, and M. Kolobielski, *J. Org. Chem.*, **22**, 1113 (1957).

(36) M. Tiffeneau and H. Cahnmann, *Bull. Soc. Chim. France*, [5] **2**, 1876 (1935).

since products formed from the  $\alpha$ -methylstyrene did not overlap with the aziridines IV and V.

**Preparation of 4-Carboethoxamino-2-methylpentene-2 (VIII).** A solution of 1.5 g (0.005 mole) of the N-carboethoxy-2-amino-3-iodo-4-methylpentane (from *trans*-4-methylpentene-2) and 2.5 g (0.025 mole) of triethylamine in 50 ml of absolute ethanol was stirred at room temperature for 3 hr, poured into water, and extracted with ether. From the washed ether solution, a residue was obtained that yielded VIII by gas chromatography on column B (145°). It was identified by its infrared, nmr, and mass spectra. The infrared spectrum showed N-H at 3450 (sharp) and 3350 (broad), carbonyl at 1715  $\text{cm}^{-1}$ . The nmr spectrum showed the ethoxy  $\text{CH}_3$  at  $\delta$  1.22 (t), ethoxy  $\text{CH}_2$  at 4.10 (q);  $\text{CH}_3$  at 1.17 (d),  $\text{CH}_2$  groups at C-2 1.72 and 1.74; N-C-H at 4.0–4.7 (m); olefinic C-H and N-H at 4.7–5.2 (m); all with the proper integrals. The parent peak in the mass spectrum was, as expected, at  $m/e$  171; ratio  $(M + 1)/M$

10.4% (calcd for  $\text{C}_9\text{H}_{17}\text{NO}_2$ : 10.6%); base peak at  $m/e$  156, corresponding to the loss of a methyl to give  $\text{EtOOC-NH-CH-CH}=\text{C}(\text{CH}_3)_2$  for this latter peak, the ratio of  $(M + 1)/M$  was found as 8.5% (calcd for  $\text{C}_8\text{H}_{15}\text{NO}_2$ : 9.3%).

**Analysis for 4-Carboethoxamino-2-methylpentene-2 (VIII).** A reaction mixture from a run with 1.5% olefin concentration (*cis*-olefin) was analyzed for VIII on column B. A trace of material with the retention time of VIII was noted; its peak area was 2.4% of that of the combined aziridines, IV + V.

## Disproportionation of Organic Polysulfides

T. L. Pickering, K. J. Saunders, and A. V. Tobolsky

*Contribution from the Frick Chemical Laboratory, Princeton University, Princeton, New Jersey 08540. Received September 28, 1966*

**Abstract:** The thermal decomposition of dimethyl tetrasulfide and trisulfide at 80° has been followed by the use of nmr spectroscopy. In the first case, dimethyl tri-, tetra-, penta-, and hexasulfides were found in the early stages of the decomposition. In the second case, decomposition was much slower and dimethyl di-, tri-, and tetrasulfides were initially present. Addition of a stable free radical to dimethyl tetrasulfide was found to inhibit the formation of tri- and higher polysulfides. A mechanism for the decomposition of dimethyl tetrasulfide is suggested.

The facile thermal decomposition of organic tetra- and trisulfides has been known for many years. For example, Twiss recorded that diethyl tetrasulfide gives diethyl trisulfide and free sulfur on distillation *in vacuo*;<sup>1</sup> Jones and Reid reported that the same tetrasulfide decomposes to diethyl disulfide and sulfur at 140–150°;<sup>2</sup> Bloomfield found that dicyclohexyl tetrasulfide gives a material of reduced sulfur content and dicyclohexyl hexasulfide when heated at 140–150°;<sup>3</sup> Fuson, *et al.*, found that bis(2-chloroethyl) trisulfide gives a mixture of bis(2-chloroethyl) disulfide, higher sulfides, and sulfur on heating at 145–160°;<sup>4</sup> and Guryanova, *et al.*, showed that when ditolyl trisulfide, in which the central sulfur atom is radioactive, is heated with diethyl trisulfide the latter becomes radioactive through exchange of the central sulfur atoms.<sup>5</sup> Recently we have illustrated the instability of the tetrasulfide linkage in a more quantitative manner with the finding that the dissociation energy of the tetrasulfide linkage in dimethyl tetrasulfide is only about 36 kcal/mole.<sup>6</sup>

Although the lability of the polysulfide linkage has been recognized, systematic studies of the thermal decomposition of organic polysulfides have been hindered by lack of suitable means of analysis. Because the products of decomposition are themselves thermally

unstable, quantitative data based on classical methods of separation are not only difficult to obtain but are also suspect. Recently Grant and Van Wazer have reported that various dimethyl and di-*t*-butyl polysulfides can be distinguished by nmr spectroscopy.<sup>7</sup> Using an analogous procedure we have followed the thermal decomposition of dimethyl tetrasulfide and trisulfide at 80°. Investigations into the mechanism of decomposition were also carried out.

### Experimental Section

**Reagents.** Dimethyl tetrasulfide was prepared as previously reported by us.<sup>6</sup> Dimethyl trisulfide was prepared by an analogous procedure using sulfur dichloride (Matheson Coleman and Bell) distilled immediately before use, bp 57–58°. The trisulfide had bp 56–57° (13 mm) (lit. 59° (12 mm)),<sup>8</sup> 54–55° (11 mm),<sup>9</sup> 58–59° (15 mm)<sup>10</sup>;  $n_D^{20}$  1.5973 (lit.<sup>10</sup> 1.5972). The yield was 87%.

**Anal.** Calcd for  $\text{C}_2\text{H}_6\text{S}_3$ : C, 18.95; H, 4.78; S, 76.24. Found: C, 18.99; H, 4.75; S, 76.30.

$\beta$ -(Phenyl nitrogen oxide)- $\beta$ -methylpentan- $\delta$ -one oxime (hereafter called Banfield's free radical) was prepared by the method of Banfield and Tüdös.<sup>11,12</sup> Azobisisobutyronitrile (Du Pont) was used as received.

**Procedure.** The polysulfide under investigation (0.6 ml) and a small sealed capillary tube containing tetramethylsilane were placed in a precision-bore Pyrex nmr tube to which a standard taper joint had been attached. The tube was then degassed and sealed off under a slight pressure of nitrogen following the method previously

described by us.<sup>6</sup> The tube was heated at 80° in a bath completely protected from light. It was removed at intervals, quenched in liquid nitrogen, and allowed to attain room temperature. The nmr spectrum was taken and the tube returned to the bath.

In the other systems investigated the following materials were used: (a) dimethyl tetrasulfide (1.12 g), Banfield's free radical (0.100 g), carbon tetrachloride (0.8 ml); (b) dimethyl trisulfide (0.668 g), dimethyl tetrasulfide (0.014 g); (c) dimethyl trisulfide (0.75 ml), azobisisobutyronitrile (0.107 g); (d) dimethyl trisulfide (0.25 ml), benzene (0.5 ml); and (e) dimethyl trisulfide (0.25 ml), nitrobenzene (0.5 ml). In each case 0.6 ml of solution was placed in an nmr tube and treated as above.

**Nmr Analysis.** Grant and Van Wazer<sup>7</sup> found that the position of the methyl resonance in a dimethyl polysulfide was progressively shifted to lower fields as the number of sulfur atoms in the polysulfide increased. In mixtures of polysulfides and in the presence of solvents the positions of the peaks, relative to tetramethylsilane, were variable, depending on the composition of the system. However, the positions of the peaks, relative to each other, were practically constant over a range of systems.

In the present work the peaks obtained from the various reaction mixtures were assigned as due to dimethyl di-, tri-, and tetrasulfides by comparison with positions and separation of the peaks obtained from authentic samples and mixtures thereof. The assignment of peaks to higher sulfides was made on the assumption that the extent of deshielding is a smooth monotonous function of the number of sulfur atoms in the polysulfide.

The difference in chemical shift of polysulfides differing by one sulfur atom was averaged over a selection of spectra obtained. The values obtained are shown in Table I; for comparison values computed from the data of Grant and Van Wazer are also given.

**Table I.** Differences in Chemical Shifts of Dimethyl Polysulfides

$\Delta S_{1,2}^a$	$\Delta S_{1,3}^a$	$\Delta S_{1,4}^a$	$\Delta S_{2,3}^a$	
9.1	5.7	1.7	1.2	This work
8.8	5.6	1.0	1.9	Ref 7

<sup>a</sup>  $\Delta S_{m,n}$  is equal to the chemical shift of the methyl protons in  $\text{MeS}_m\text{Me}$  minus the chemical shift of the methyl protons in  $\text{MeS}_n\text{Me}$  in cps.

The nmr spectra were taken on a Varian A-60 high-resolution spectrometer using a sweep width of 50 cps and a sweep time of 250 sec. Peak areas were determined by machine integration. For each spectrum the area of each peak assigned to a particular polysulfide was expressed as a percentage of the total area due to all the polysulfides present. Since all dimethyl polysulfide molecules contain the same number of hydrogen atoms, this percentage area is equal to the number of molecules of the particular polysulfide present expressed as a percentage of the total number of polysulfide molecules present, i.e., to the molar percentage.

## Results

The percentage molar distributions of dimethyl polysulfides in the systems investigated at various time intervals are shown in Tables II–VIII. The quantities given are probably accurate to about  $\pm 2$ . (Several duplicate nmr measurements were made in each case.) In no spectrum obtained was there evidence of monosulfide, and hydrocarbons were not formed since the sum of the peak areas remained constant relative to the peak area given by the tetramethylsilane standard. The constancy of the  $\text{CH}_3:\text{S}$  mole ratio in each system investigated shows that in no case is free sulfur formed in detectable quantity.

## Discussion

In an earlier publication<sup>6</sup> we suggested that the primary mode of decomposition of dimethyl tetrasulfide was symmetrical homolytic cleavage of the tetrasulfide linkage. Our present findings are in accord with this suggestion.

<sup>a</sup> No Me<sub>2</sub>S<sub>5</sub> or Me<sub>2</sub>S<sub>6</sub> were found.

The absence of dimethyl disulfide in the early stages of the decomposition of dimethyl tetrasulfide indicates that only symmetrical cleavage of the tetrasulfide linkage occurs. Unsymmetrical cleavage would give rise to MeS· and MeS<sub>3</sub>· radicals. The MeS· radical would be expected to give rise to dimethyl disulfide by coupling or by reaction with a polysulfide molecule. In the decomposition of dimethyl trisulfide, where only unsymmetrical cleavage can occur, dimethyl disulfide is a primary decomposition product.

It has been suggested that MeS<sub>x</sub>· radicals, where  $x > 1$ , can be stabilized by a resonance interaction with the adjacent S atoms.<sup>13,14</sup> The estimated dissociation energy of the S-S bond in polymeric S is about 33 kcal/mole,<sup>15</sup> not very different from the value of the dissociation energy of dimethyl tetrasulfide. This indicates that if such stabilization exists, only two or three sulfur atoms are effective in the delocalization. If more were involved, one would expect a substantially larger difference in the dissociation energy of these two materials.

A crude estimate of the magnitude of the stabilization can be made as follows. The dissociation energy of dimethyl disulfide is known to be about 70 kcal/mole.<sup>16</sup> The difference between this value and the 36 kcal/mole found for the dissociation energy of dimethyl tetrasulfide may be attributed to the stabilization each of the fragments from dimethyl tetrasulfide derives from delocalization. This stabilization is thus (70-36)/2 or about 17 kcal/mole. From the arguments given above we would expect that the amount of stabilization available to a fragment such as MeS<sub>3</sub>· would not be greater than about 20 kcal/mole. Thus symmetrical cleavage of the tetrasulfide linkage would give two stabilized fragments with roughly 34 kcal/mole of "delocalization" energy. Unsymmetrical cleavage would give an MeS· fragment, which cannot be stabilized, and an

MeS<sub>3</sub>· fragment, which is stabilized to the extent of ca. 20 kcal/mole or less. Thus unsymmetrical cleavage would result in the loss of about 14 kcal/mole in stabilization energy in the products and should be very unfavorable.

Table IV shows that the decomposition of dimethyl tetrasulfide is completely suppressed by addition of a free-radical scavenger. From the rate constant for cleavage of the tetrasulfide linkage reported earlier<sup>4</sup> it was possible to compute how long it would take for the scavenger to be consumed. Under our conditions about 47 min should have been required. Most of the scavenger was consumed after 45 min. This could be ascertained by the appearance of a resolvable nmr spectrum at the end of this period. (No resolvable spectrum could be obtained in the presence of the initial amount of free-radical scavenger, owing to the presence of the unpaired electron.) This offers convincing proof that radicals are involved in this decomposition; otherwise it is difficult to envisage a way of removing the unpaired spin. Dimerization of the free-radical scavenger may be ruled out by the observation that no decomposition occurs during the first hour in the presence of the scavenger whereas about 25% of the initial amount of dimethyl tetrasulfide is decomposed in a similar period in the absence of the scavenger. After the free-radical scavenger has been consumed, the decomposition proceeds in virtually identical fashion with that observed in the absence of inhibitor.

We wish to suggest the following mechanism for the decomposition of dimethyl tetrasulfide

It may be noted that  $\alpha$  attack by MeS<sub>3</sub>· radicals on dimethyl tetrasulfide results in no new products. The same is true of  $\beta$  attack by MeS<sub>2</sub>· radicals on dimethyl tetrasulfide. The higher polysulfides can undergo cleavage at these temperatures and give rise to the same type of reactions as described above for dimethyl tetrasulfide. We also believe that reactions such as

are very unfavorable under our reaction conditions since the MeS· radical would almost certainly give rise to dimethyl disulfide (which was not observed until after long periods of heating).

The greater thermal stability of the trisulfide linkage as compared to the tetrasulfide linkage is apparent from the slower rate of decomposition of dimethyl trisulfide. If this decomposition involves homolytic cleavage, this observation is to be expected from our previous remarks concerning stabilization of the fragments.

An attempt was made to react dimethyl trisulfide with Banfeld's free radical in a manner analogous to that used with the tetrasulfide. However, the slow rate of decomposition and the thermal instability of the free-radical scavenger combined to yield inconclusive results.

(13) G. Gee, *Sci. Progr.* (London), **43**, 193 (1955).(14) G. Gee, F. Fairbrother, and G. T. Merrall, *J. Polymer Sci.*, **16**, 459 (1955).(15) D. M. Gardner and G. K. Fraenkel, *J. Am. Chem. Soc.*, **78**, 3279 (1956).(16) H. Mackle, *Tetrahedron*, **19**, 1159 (1963).

dition of a small amount (2% molar) of dimethyl disulfide to the trisulfide did not accelerate the rate of decomposition of the latter. This indicates that a free-radical chain reaction does not occur at any appreciable

A similar conclusion follows from consideration of the influence of azobisisobutyronitrile on the decomposition of dimethyl trisulfide. The initial rate of formation of dimethyl tetrasulfide is slightly accelerated, as the rate of production of disulfide is unaffected. It is almost certain that the role of the azobisisobutyronitrile is to generate isobutyronitrile radicals which subsequently attack the trisulfide. The following reactions are possible.

Reaction 8 may be excluded since the formation of  $\text{Me}_2(\text{MeS}_2)\text{CCN}$  radicals would almost certainly result in the decomposition of dimethyl disulfide. For the same reason,  $\text{MeS}_2\cdot$  radicals produced cannot participate in reaction 7 but must undergo recombination to give dimethyl tetrasulfide.

These last two experiments show that the decomposition of dimethyl trisulfide does not occur by a free-radical chain reaction initiated by the fragments of homolytic dissociation. A nonchain radical mechanism is possible and the similarity in the rates of decomposition in the solvents benzene and nitrobenzene is in accordance with this mechanism. However, we feel that our evidence is not sufficient to allow a firm conclusion to be made at the present time.

Preliminary studies in our laboratories have indicated that polysulfenyl radicals,  $\text{RS}_x\cdot$ , where  $x > 1$ , have substantially different reactivity than sulfenyl radicals,  $\text{RS}\cdot$ .<sup>17</sup> In the past workers have found that non-Markovnikov addition of sulfenyl radicals to olefins is suppressed in the presence of sulfur and polysulfides.<sup>2,3</sup> Such results have been explained in terms of an ionic addition caused by the presence of sulfur. While such explanations are quite reasonable, we suggest that they be viewed with due caution until the reactions of polysulfenyl radicals are more completely understood.

## The Vacuum Ultraviolet Photochemistry of *o*-Xylene

Harold R. Ward

*Contribution from the Metcalf Chemical Laboratories, Brown University, Providence, Rhode Island 02912. Received December 9, 1966*

**Abstract:** The vapor-phase photolysis of *o*-xylene has been investigated using light of 1600–2100 Å. With the exception of a small amount of benzocyclobutene which is formed by vacuum ultraviolet photolysis, the same products are formed as those produced by irradiation with 2537-Å light (toluene, *m*-xylene, *p*-xylene, and *o*-ethyltoluene). This coincidence of products suggests that both photolyses may proceed through a common set of reactive intermediates. Fluorescence measurements, as well as the effect of added inert gases on the reaction, indicate that the first excited singlet and lowest lying triplet states are not suitable choices for such common intermediates. The intermediacy of highly vibrationally excited ground electronic states seems to be most consistent with the available facts. The mechanism of formation of benzocyclobutene has been investigated by deuterium labeling, and found to proceed by the loss of a single hydrogen (or deuterium) atom from each methyl group, rather than loss of molecular hydrogen from one methyl group. The construction of lamps which emit  $10^{16}$  to  $10^{17}$  quanta/sec in the vacuum ultraviolet is described.

The interest in the photochemical reactions of simple, noncondensed, aromatic hydrocarbons has recently heightened by the reports of Wilzbach and Kaplan of rearrangements to the nonbenzenoid "isomers" under irradiation at the 2537-Å mercury line. In the case where the benzene ring is heavily substituted with *tert*-butyl groups (e.g., 1,2,4-tri-*tert*-butylbenzene) these isomers are isolable;<sup>1</sup> with smaller groups the intermediacy of the isomers is inferred from the isomerization of substituted compounds.<sup>2</sup> These reactions occur with low quantum efficiencies, typically about 0.01.

K. E. Wilzbach and L. Kaplan, *J. Am. Chem. Soc.*, **87**, 4004

Irradiation with light of wavelengths of less than 2000 Å is expected to bring about reactions much more efficiently. This expectation is based on a report<sup>3</sup> that no fluorescence was observed when simple aromatics (benzene, toluene, *p*-xylene, and mesitylene) were irradiated in the vapor phase at wavelengths corresponding to their second and third absorption bands, approximately 1600–2100 Å. It is reasonable that the failure to observe light emission may result from an efficient predissociation path available to the excited molecule.

Since only fragmentary reports of the vacuum ultraviolet photochemistry of aromatics were available, an

Figure 1. Vacuum ultraviolet discharge lamp: a, discharge tube; b, cooling jacket; c, photolysis cell.

investigation of the photolysis of very simple members of this compound class has been initiated in this laboratory. This paper is a report of the results observed from a single compound, *o*-xylene, and of the construction of light sources suitable for such an investigation.

### Results

**Vacuum Ultraviolet Light Sources.** The most obvious practical reason for the neglect of studies of vacuum ultraviolet photochemistry has been the difficulty of the construction of sources of suitable intensity and stability. The production of very pure fused silica (Suprasil or Spectrosil) has been of great assistance in the solution of such problems. Lamps constructed of this material transmit light down to about 1600 Å and do not appear to degrade with use (as does lithium fluoride). Also, such lamps are relatively sturdy, and the organic polymers that are frequently deposited during photolyses are easily removed from them.

Two lamp designs were used in the present investigation; both were constructed of Suprasil where vacuum ultraviolet light transmission was required, and of ordinary fused silica elsewhere. Both lamps consisted of a discharge tube surrounded by a toroidal cell. One lamp was filled with xenon at a pressure of 190 torr as suggested by Wilkinson and Tanaka,<sup>4</sup> and powered by a 2450-mc microwave generator. The discharge was contained in a Suprasil tube, part of which was surrounded by a quartz jacket which formed the photolysis cell; the unjacketed portion of the tube was inserted into a slotted wave-guide termination of the generator. The output of the lamp was inspected with a vacuum monochromator, and it agreed well with the published data.<sup>4</sup> The principal ultraviolet output is a continuum which rises steeply from the Suprasil cutoff at 1600 Å to a maximum at 1760 Å and tails off to 2200 Å. No other radiation is observed until a few weak bands begin at about 3000 Å. The output of the lamp was about  $6 \times 10^{15}$  quanta/sec as measured by oxygen actinometry. The inner wall of the cell compartment was heated by the discharge to about 300°.

The second lamp design interposed a cooling jacket between the discharge and the photolysis cell (see Figure 1). The cell temperature was controlled by electrically heating the outer jacket and forcing nitrogen from a liquid nitrogen boiler through the inner cooling jacket. This lamp was filled with oxygen at 0.3–0.6 torr, and was powered in the same manner as the xenon

lamp. The principal light output was a series of sharp lines beginning at 1600 Å and falling off to 2200 Å, with no further radiation at increasing wavelengths until a few weak and widely spaced lines appeared at 2800 Å. Approximately 95% of the ultraviolet light output below 2800 Å is between 1600 and 2000 Å. Intensity by oxygen actinometry was  $10^{16}$  to  $10^{17}$  quanta/sec, depending on the power input to the lamp. Temperatures in the cell could be varied from below 0 to 280°. The oxygen discharge appears to offer significant advantages over the xenon discharge in intensity, reproducibility, and cost. Since no particular care was used to purify the oxygen it is probable that impurities are present in the discharge, and there is some evidence that they are necessary to maintain the discharge.<sup>6</sup>

**Photolysis with Vacuum Ultraviolet Radiation.** The products obtained in the vacuum ultraviolet vapor-phase photolysis of *o*-xylene are listed in Table I. These products were formed in approximately the same ratios by both the xenon and oxygen lamps described above; the reported distributions are for photolysis with the oxygen lamp. The conversions in all photolyses were kept to less than 1% (and more usually <0.3%) to ensure that effectively all of the radiation was absorbed by the reactant. Thus direct photolytic destruction of products was prevented. Further reactions of products, photosensitized by *o*-xylene molecules, is of course not eliminated by this precaution.

Table I. Products of the Vapor-Phase Photolysis of *o*-Xylene<sup>a</sup>

	Vacuum ultraviolet, <sup>d</sup>		2537 Å		<i>c</i>
	Static	Flow	250°	40°	
<del>Xenon</del>	2	<i>b</i>	<i>b</i>	<i>b</i>	0.6
Toluene	30	<i>b</i>	<i>b</i>	16	15.6
Ethylbenzene	3	<i>b</i>	<i>b</i>	<i>b</i>	0.5
<i>m</i> -Xylene	39	88	82	64	68.4
<i>p</i> -Xylene	5	5	10	7	6.2
Benzocyclobutene	5	<i>b</i>	<i>c</i>	<i>c</i>	<i>c</i>
<i>o</i> -Ethyltoluene	15	<i>b</i>	2	10	7.3
<i>m</i> -Ethyltoluene	1	<i>b</i>	<i>b</i>	2	1.4

<sup>a</sup> The data are in mole %, normalized to 100% for the products reported. <sup>b</sup> Product present in minor amounts, less than 1 mole %. <sup>c</sup> Product could not be detected, <0.01 mole %. <sup>d</sup> The reported percentages are averages of analyses of three photolyses; the agreement was usually to  $\pm 1\%$  or better between the individual photolyses. <sup>e</sup> Calculated from data reported by Wilzbach and Kaplan.<sup>1b</sup>

Photolyses were carried out in both static and flow systems. The pressure of reactant in the photolysis cell in the static system was controlled by thermostating a reservoir of liquid *o*-xylene connected to the cell at 25°. The equilibrium vapor pressure is sufficiently high at this temperature to ensure that more than 99% of the incident light was absorbed by the sample.<sup>7</sup>

(5) The Suprasil cutoff at 1600 Å prevents photoionization of *o*-xylene, which does not set in until wavelengths of less than 1500 Å are reached.

(6) Lamps worked best with oxygen flowing past the discharge tube during the operation. Sealed lamps frequently failed after several hours use, and one acceptable explanation is that "impurities" necessary for breakdown were destroyed during the first hours of operation.

(7) Calculated from the absorption spectra published by J. R. Platt and H. B. Klevens, *Chem. Rev.*, 41, 301 (1947).

(4) P. G. Wilkinson and Y. Tanaka, *J. Opt. Soc. Am.*, 45, 344 (1955).

ie flow photolyses the *o*-xylene sample was carried h the cell in a helium stream at a total pressure atm. The concentration of *o*-xylene in the was monitored by a thermal conductivity cell e products and unreacted *o*-xylene were trapped he stream in a trap cooled with liquid nitrogen. me products were formed in both systems, but ios were changed appreciably and the quantum or product formation ( $\Phi$ , defined as quantum yield nation for  $C_6$  to  $C_9$  compounds) was lower in the ystem ( $\Phi = 0.10$ ) than in the static system ( $\Phi$  ).

tively large increases of the temperatures of the : (from 150 to 240°) for photolyses in the flow caused little change in product composition, but increase in quantum yield:  $\Phi = 0.02$  at 150° = 0.1 at 240°. This increase in  $\Phi$  is at least par- and perhaps completely) due to the diminished ion of polymer on the lamp jacket at the higher ature.

s spectral analysis of the noncondensable gas 'K) present after a static photolysis indicated that en was present along with smaller amounts of ne. Polymer formation was visible only when np was cooled (to about 150° or lower) or when ounts of material were passed through the lamp flow system. The visible polymer at low lamp atures probably resulted from further photolysis eric" products which condensed on the "cold" jacket. Some dimeric products are formed in its much smaller than the volatile products. rincipal dimeric product has been identified by on time as *o,o'*-dimethylbibenzyl; other com- s of similar molecular weight are present but have en identified.

mer is certainly formed in photolyses at higher atures, because a slight decrease in light output lamp (about 10%) is observed by oxygen actin- following a photolysis.<sup>8</sup> Some ring fragmenta- oducts,  $C_6$  and less, were also formed in small ts (less than 1 mole %), but could not be repro- y measured and are not included in the reported um yields.

olysis at 2537 Å. The photochemistry of *o*- at 2537 Å has been reported by Wilzbach and .<sup>2b</sup> Their results and those obtained under conditions (static system, 7 torr *o*-xylene pres- 10°, low-pressure mercury lamp) in this study excellent agreement. When the experiment eated using a sample heated to 250° the product hanged only slightly.

lysis. To ensure that the products formed in ysis at 250° were not merely pyrolytic products, simple pyrolysis experiments were carried out. *o*-xylene was passed through a quartz tube at a helium stream, no observable reaction occurred. 1° a very small conversion was observed to prod- xpected from free-radical reactions: benzene, z, *o*-ethyltoluene, and *o,o'*-dimethylbibenzyl. izocyclobutene or *m*- or *p*-xylene was formed.

uantum yields for polymer formation were not determined quan- because a photolysis to 1 % conversion on samples of 50 mg did sufficient material for even approximate gravimetric determina- otolysis to much higher conversions or on larger quantities of ave polymer coatings on the lamp windows which made determinations inaccurate.

## Discussion

The most striking feature of the results reported in Table I is the close correspondence between the products formed by irradiation at 2537 Å and with vacuum ultra-violet radiation. Except for the benzocyclobutene which is formed only in the vacuum ultraviolet photolysis, all of the appreciable products (greater than 1 mole %) formed at 2537 Å are also formed by the vacuum ultraviolet. It is possible that this similarity is merely coincidental and that excitation at these different energies leads to the same products by different paths; no data are in hand which exclude this possibility. However, an entirely reasonable alternative is that both photolytic systems lead to a common set of reactive intermediates which proceed to the stable products. Of the two hypotheses, the second is best supported by the product studies, and leads to interesting speculation as to the possible identities of such intermediates.

A summary of the facts which are relevant to such a speculation is presented below. These facts have been gathered from the results of the closely related photolysis of benzene,<sup>9</sup> and from fluorescence studies in the vacuum ultraviolet<sup>3</sup> as well as from the data reported in this study.

1. Fluorescence measurements<sup>3</sup> with benzene, toluene, and *p*-xylene (vapor phase) clearly indicate that excitation in the first allowed absorption band ( $\lambda < 2000$  Å) does not lead to light emission. It has been concluded from this study that neither the first excited singlet state ( $S_1$ ) or the lowest triplet state can be formed by such irradiation. Similar studies have not been done for *o*-xylene, but the spectral assignments,<sup>7</sup> absorption intensities,<sup>7</sup> and photochemistry<sup>10</sup> are so similar for *o*- and *p*-xylene that the assumption that  $S_1$  and the lowest triplet are not formed by vacuum ultraviolet photolysis is a satisfactory one.

2. The addition of inert gases or an increase in reactant pressure decreases the observed quantum yield of benzene disappearance at 1849 Å<sup>11</sup> and a similar effect of inert gas is observed on the 2537-Å isomerization of *m*-xylene.<sup>2b</sup> Helium (1 atm) lowered the  $\Phi$  from *o*-xylene by 40%.

3. When oxygen is added to photolysis samples, it is found to be only slightly more effective in lowering conversions than are other foreign gases. Thus oxygen was only three times as effective in quenching *m*-xylene isomerization as was nitrogen (both at 100 torr, *m*-xylene at 5–7 torr).<sup>2b</sup> Oxygen (2 torr) had no effect on the disappearance of benzene (1 torr) with 1849-Å irradiation.<sup>11</sup>

4. Pyrolysis of *o*-xylene at 550° led to a few of the photolysis products in very low conversions, but the major product, *m*-xylene, was not formed.

5. Product ratios from both 2537 Å and the vacuum ultraviolet photolysis of *o*-xylene were changed by changes in temperature and by addition of inert gases.

(9) There is every reason to believe from spectral assignments<sup>7</sup> that the same excited states are being examined in each case. Photoproducts are very different in the two cases because the principal reactions which occur with the xylenes are either reiterative (isomerization) or impossible (loss of methyl or benzylic hydrogen) with benzene. As a result no photoproducts form from benzene with 2537-Å radiation in the vapor phase [J. N. Pitts, Jr., J. K. Foote, and J. K. S. Wan, *Photochem. Photobiol.*, 4, 323 (1965)], and the principal reaction with vacuum ultraviolet irradiation is the formation of fulvene [H. R. Ward, J. S. Wishnok, and P. D. Sherman, Jr., *J. Am. Chem. Soc.*, 89, 162 (1967)].

(10) H. R. Ward, unpublished data.

(11) K. Shindo and S. Lipsky, *J. Chem. Phys.*, 45, 2292 (1966).

The excited state which *prima facie* is expected to be common between excitation at 2537 Å and by the vacuum ultraviolet is the  $S_1$  state, since intersystem crossing from higher singlets to the first excited singlet is usually thought to be very efficient.<sup>12</sup>

The  $S_1$  state seems unlikely as a common reactive intermediate in this case for several reasons. First, fluorescence studies<sup>3</sup> (1) strongly suggest that this state cannot be formed by vacuum ultraviolet irradiation. Second, inert gas gives almost no quenching of benzene fluorescence<sup>13</sup> (when pressures in the range of these experiments are considered), but does quench *m*-xylene isomerization.<sup>2b</sup> Finally, oxygen has no effect on benzene disappearance at 1849 Å (3) even though it is known to quench the  $S_1$  state.<sup>11</sup> The presence of any triplet state in the reaction scheme also can be eliminated by the small effect of added oxygen.<sup>14</sup>

A higher singlet,  $S_n$ , can hardly be reached by 2537-Å excitation, but can be eliminated as an intermediate leading directly to products even from vacuum ultraviolet photolysis, because its lifetime is so short ( $10^{-12}$  sec) that no effect of added inert gas would be expected<sup>3</sup> (collision times under these conditions are about  $10^{-9}$  to  $10^{-10}$  sec). The most reasonable remaining alternatives for common reactive intermediates are various highly vibrationally excited ground electronic states ( $S_0^*$ ). Thus a molecule excited to an  $S_n$  state might undergo rapid internal conversion to such a  $S_0^*$  state; conversion from  $S_1$  to  $S_0^*$  must compete with fluorescence. The higher quantum yield for product formation with the vacuum ultraviolet than with 2537 Å is consonant with such a system.

The effect of oxygen in decreasing the quantum yield of isomerization of *m*-xylene may be due to quenching of  $S_1$  before internal conversion occurs. Added inert gases would be expected to decrease  $\Phi$  of product formation by collisional deactivation. This postulate is also consistent with the observations listed in 1. Similar arguments have been used by Shindo and Lipsky<sup>11</sup> to propose an excited ground state in benzene photolysis.

The sensitivity of product ratios to changes in temperature and added foreign gases indicates that the products do not proceed directly from any single excited state. A single intermediate which could lead to such a variety of products would be very difficult to visualize in any case. It is not possible from the available data to say anything about which vibrational states might be involved, but a close inspection of the product ratios reported in Table I leads to some interesting suggestions. Thus at constant temperature, introduction of 1 atm of helium (in the vacuum ultraviolet system) causes a decrease in  $\Phi$  which is almost entirely in products involving bond cleavage and bond formation (called, for convenience, decomposition products). Isomerization proceeds almost unhindered. This is consistent with a model in which highly vibrationally excited molecules lead to isomeriza-

tion in a time comparable to collisional times and other vibrational states (probably lower lying than those leading to isomerization) lead less rapidly to decomposition. Although energy surfaces are so complex as to be almost abstract for molecules as complicated as *o*-xylene, this situation is approximated by a surface leading to isomerization which crosses the ground-state surface at a high vibrational level, and a surface which crosses at a lower level leading to decomposition products. Reactions which lead to isomerization probably give the initially formed isomer at a high vibrational level. An increase in sample or foreign gas pressure should operate to stabilize the isomer and prevent its further decomposition. This expected effect is also compatible with the observed results.

Such a model is also consistent with the effect of temperature on product distribution in 2537-Å radiation. Internal conversion from the  $S_1$  level would probably enter the ground-state manifold at a level lower than that for  $S_n$  crossing. Raising the sample temperature would give a greater number of molecules the vibrational energy necessary to isomerize. Such a model predicts that hot-tube pyrolysis should lead mostly to decomposition, since the vibrational levels are populated from the bottom in a Boltzmann fashion and excited molecules would be "siphoned" off onto the decomposition route before gaining enough energy to isomerize. The conceptual model is of course highly oversimplified. It is probably more reasonable to postulate that each decomposition product results from different levels of vibrational excitation. Also, if the simple model were to be strictly applied, it would predict a larger relative percentage of isomerization in vacuum ultraviolet photolysis than is actually observed.

Wilzbach and Kaplan found no evidence of *p*-xylene at low photolytic conversions of *o*-xylene vapor.<sup>2a</sup> In vacuum ultraviolet photolysis, *p*-xylene is present even at conversions of 0.05%, and in a relatively constant ratio with *m*-xylene, so that it is most unlikely that *p*-xylene forms from a further isomerization of *m*-xylene. The suggestion of Wilzbach and Kaplan that isomerization proceeds through intermediates of benzvalene (I) and prismane types (II) has considerable

I

II

experimental support. A benzvalene intermediate formed from *o*-xylene can lead only to *m*-xylene (or back to *o*-xylene), all three isomers can be formed from the dimethylprismanes. (No stable dimethylbenzvalene or dimethylprismane has yet been detected in this system.) The suggestion of Bryce-Smith and Longuet-Higgins<sup>15</sup> that the first excited singlet state in benzene should lead to benzvalene, and the lowest triplet to prismane appears to be inapplicable to *o*-xylene at least (*vide supra*). The exact method by which isomerization occurs has not been established for the xylenes, nor has the excited state leading to isomerization been identified. Hopefully these problems will yield to experiments presently in progress.

**Mechanism of Benzocyclobutene Formation.** The only isolated product that is unique to the vacuum

violet photolysis of *o*-xylene (as compared to 2537 Å benzocyclobutene. This product must also come from some vibrationally excited and relatively lived intermediate because its yield is decreased with a decrease in temperature and by an increase in gas pressure.

To effect the formation of benzocyclobutene, two hydrogen atoms must be lost from the *o*-xylene molecule, most probably from the methyl groups. Two routes can be envisioned for this loss.

Two routes can be supported by analogy to known chemical reactions. Cleavage of C-H bonds to form benzylic radicals (as in a) has been demonstrated by Porter and Wright.<sup>16</sup> Loss of molecular hydrogen from a single carbon atom (as in b) is the preferred route of decomposition of ethane with 1470-Å photons.<sup>17</sup> The proof that benzocyclobutene is preferentially formed by path a was obtained by the photolysis of  $\alpha,\alpha,\alpha$ -trideutero-*o*-xylene. The isotopic content of the benzocyclobutene product was determined

by mass spectroscopy at low ionizing voltage. The chromatograph direct coupled to a mass spectrometer showed that 90% of the benzocyclobutene contained two deuterium atoms, and only 4%  $d_3$  and 6%  $d_1$ . This particular analysis provides a convincing demonstration of the power of this analytical combination. The photolysis was run on a 35-mg sample of deuterated material, and the product contained 3  $\mu$ g of benzocyclobutene. This amount of material would have been sufficient to obtain over 100 satisfactory analyses of product distribution (from the chromatograph trace) and isotopic composition (from the mass spectrometer output).

## Experimental Section

**Ultraviolet Lamps.** **Xenon Lamps.** Research grade (at 190 torr) was sealed in a Suprasil tube, 12 mm o.d.  $\times$  9 cm of the length was enclosed in a 20-mm o.d. quartz which was fitted with ground joints at the top and bottom.

G. Porter and F. Wright, *Trans. Faraday Soc.*, 51, 1469 (1955). R. F. Hampson, Jr., J. R. McNesby, H. Akimoto, and I. Tanaka, *J. Phys.*, 40, 1099 (1964).

The lamp was powered by inserting the unjacketed stub of the Suprasil envelope into the slotted wave guide of a PGM-100 Raytheon microwave power generator (2450 mc, 150–800 w). The lamp was cooled during operation by air blasts from several directions.

**Oxygen Lamps.** The lower 8-cm portion of a 12 mm o.d.  $\times$  16 cm Suprasil tube (0.5-mm wall) was jacketed by a 18 mm o.d. Suprasil tube carrying ground joints at the bottom and near the top ring seal. This jacket was used for cooling the lamp. The cooling jacket was in turn enclosed by a 40-mm o.d. quartz jacket, also fitted with top and bottom joints, which comprised the photolysis cell (see Figure 1). The discharge tube of this lamp was not sealed, but operated with oxygen flowing past the top of the discharge tube through a T joint. The pressure was held at 0.3–0.6 torr (as measured by a thermocouple gauge) by an adjustment of a needle valve on an oxygen cylinder leading to the T joint and a needle valve leading away from the T joint to a mechanical pump. The lamp was powered in the same manner as the xenon lamp. The light output was inspected by a Robin, 0.5-m vacuum monochromator through the top joint of the photolysis cell.

**Actinometry.** Oxygen actinometry was used to measure the output of both lamps. Oxygen was passed through the photolysis cell at 100–160 cc/min and bubbled through a dispersion tube into a 0.1 M solution of potassium iodide buffered with sodium acetate and acetic acid. The  $I_2^-$  concentration was determined spectroscopically at 350 m $\mu$ . Duplicate determinations usually agreed to  $\pm 5\%$ .

**Photolysis Technique. Static System.** The *o*-xylene sample (Phillips Petroleum Research grade) was placed in a small flask on the bottom joint of the cell of the oxygen lamp, frozen at 77°, the jacket was evacuated to 0.005 torr, and the sample was degassed by a freeze-thaw cycle. The cell was isolated by a stopcock and the sample flask thermostated at 25°. After allowing sufficient time for equilibrium to be reached, the lamp was started, and cooling nitrogen was passed through the cooling jacket. The extent of cooling was determined by the voltage on a heater in a liquid nitrogen boiler. After the photolysis, the sample was condensed in the flask and removed for analysis.

**Flow Systems.** The *o*-xylene sample was injected into a glass container installed in the place of a column in the oven of an Auto-prep gas chromatograph. The effluent stream from the thermal conductivity cell was conducted to the photolysis cell through a heated line. The temperature of the *o*-xylene was controlled by the oven thermostat, the helium flow was held constant by the chromatograph flow controller, and the *o*-xylene concentration was precisely monitored by the chromatograph detector. For sample sizes of 0.1 ml at temperatures of 40 to 50° the technique gave a nearly constant *o*-xylene concentration for greater than 90% of the photolysis time. Samples were trapped at liquid nitrogen temperature for analysis.

**Photolysis at 2537 Å.** Ten germicidal lamps (GE G25-T8) were arranged in a 26-cm diameter circle with a stainless steel reflector surrounding the lamps. The photolysis cell was a fused quartz tube, 2.54 cm o.d.  $\times$  54 cm, fitted with a sample holder and a stopcock. The sample of *o*-xylene (0.01 ml) was frozen in the sample holder, the cell was evacuated to less than 0.005 torr and isolated with the stopcock, and the sample was allowed to warm to room temperature. The cell was suspended along the vertical axis of the circle of lamps during the photolysis. For photolysis at 250°, the cell was loosely wrapped with fine resistance wire. Temperatures inside the tube were measured by a thermocouple. Heating by this method showed a variation of  $\pm 10^\circ$  along the tube; the reported temperature is an average.

**Pyrolysis.** A quartz tube 1.8 cm o.d.  $\times$  14 cm was wrapped with resistance wire for use as a pyrolysis tube. The *o*-xylene sample was passed through the tube in a helium stream, as described for the vacuum ultraviolet photolysis flow system.

**Analysis.** All analyses were done by flame-ionization gas chromatography, occasionally in conjunction with mass spectroscopy. The most useful columns were 5% DEGA-5% Bentone-34 on 100–120 mesh Chromosorb W,  $\frac{1}{8}$  in. o.d.  $\times$  20 ft, operated at about 70°. A support-coated Carbowax 1540 capillary column, 0.02 in. i.d.  $\times$  50 ft, was useful in separating benzocyclobutene from the ethyltoluenes. Analysis for dimeric hydrocarbons was done on Silicone SE-30, Silicone QF-1, and DEGA-Bentone-34 columns at higher temperatures (100–140°). Quantitative determinations were averages of triplicate analyses, and areas were measured by planimeter or disk integrator and corrected for sensitivity to the flame detector to give the mole fraction. Identification was by comparison of retention times with known compounds on at least two (and

usually three) columns, and by comparing the fragmentation pattern in the mass spectrum. In the gas chromatograph-mass spectrometer combination, a Varian Aerograph, Model 204-2, was connected by a low volume heated line, fed through an effluent stream splitter, to the helium concentrator of a Perkin-Elmer-Hitachi RMU 6-D.

**Synthesis of  $\alpha,\alpha,\alpha$ -Trideuterio-*o*-xylene.** A solution of 2.65 g (0.0175 mole) of methyl *o*-toluate and 0.6 g of lithium aluminum deuteride (Metal Hydrides) in 10 ml of ethyl ether was stirred at reflux for 12 hr. Work-up with aqueous acid gave 2.14 g (0.0172 mole) of a white solid, mp 31–33° (lit.<sup>18</sup> *o*-methylbenzyl alcohol mp 34°). The crude dideuterio alcohol (1 g) was added to 20 ml of cold, freshly distilled thionyl chloride, and the solution was slowly warmed to the boiling point and refluxed until gas evolution ceased. Excess thionyl chloride was removed on a rotary evaporator, and small portions of pentane were added and removed under vacuum to flush out the remaining traces of thionyl chloride. The resulting clear oil was dissolved in 20 ml of dry tetrahydrofuran and stirred

at reflux under nitrogen with 0.26 g of lithium aluminum deuteride. The reaction mixture was acidified, and the product *o*-xylene was extracted into a known volume of pentane. Comparison of the gas chromatogram of this solution with a standard mixture indicated that 0.76 g of the deuterated *o*-xylene was present (theory, 0.88 g). The *o*-xylene was isolated by preparative gas chromatography to ensure purity of the sample. Analysis by mass spectroscopy at reduced ionization voltage showed the *o*-xylene to be 98%  $d_4$  and 2%  $d_2$ , with no detectable amounts of  $d_1$  or  $d_0$ .

**Acknowledgments.** The support of this research by the National Science Foundation (GP-3496) is gratefully acknowledged. The mass spectrometer used in this investigation was purchased under a National Science Foundation Research Instrument Grant. Mr. John S. Wishnok and Mr. Charles I. Barta participated in the development of the oxygen lamp and in measuring its spectral output.

## Photochemistry of Sodium 9-Anthroate in Aqueous Solution<sup>1</sup>

Anne W. Bradshaw and O. L. Chapman

Contribution from the Department of Chemistry, Iowa State University of Science and Technology, Ames, Iowa 50010. Received November 5, 1966

**Abstract:** The photochemistry of sodium 9-anthroate in aqueous solution has been investigated. Earlier reports that irradiation of sodium 9-anthroate in the presence of air gives photodimer and anthraquinone have been confirmed, and carbon monoxide, 10,10'-bianthrone, and anthracene have also been isolated. In degassed solutions sodium 9-anthroate gives anthrol anion and carbon monoxide. Air oxidation of the anthrol anion is responsible for formation of anthraquinone and 10,10'-bianthrone. The photochemical isomerization of sodium 9-anthroate to anthrol anion is considered to be analogous to the photoisomerization of 9-nitroanthracene.

Recent investigations of vinyl<sup>2,3</sup> and aryl<sup>2,4</sup> nitro compounds have uncovered photochemical rearrangements in which the nitro group isomerizes to a nitrite ester which then gives rise to products.

Irradiation ( $\lambda < 410 \text{ m}\mu$ ) of 9-nitroanthracene gives, for example, 10,10'-bianthrone as the major product and lesser amounts of anthraquinone and anthraquinone monooxime,<sup>2,5</sup> while  $\beta$ -methyl- $\beta$ -nitrostyrene gives 1-phenyl-1-oximino-2-propanone.<sup>2,3</sup>

As one aspect of our investigation of these rearrangements, we have considered whether the carboxylate anion which is isoelectronic with the nitro group might show related rearrangements. Both the nitro group and the carboxylate group are capable of  $n \rightarrow \pi^*$  and  $\pi \rightarrow \pi^*$  transitions. Sodium 9-anthroate was selected for initial study because of its relationship to 9-nitroanthracene. Weigert and Ludwig have reported<sup>6</sup> that irradiation of aqueous solutions of sodium 9-anthroate which were open to air gave a precipitate (anthraquinone)

odimer and anthraquinone was confirmed, and 10,10'-bianthrone and anthracene were observed as products. Flushing the solution with purified nitrogen<sup>9</sup> during the irradiation (which should remove most all oxygen from the solution) had little effect on product composition. A change in concentration of sodium 9-anthroate from 0.040 to 0.0045 M reduced the yield of dimer slightly but did not affect the yields of other products significantly. Use of light of wave-

Rigorous degassing by freeze-thaw cycles was not practical for this scale work. Nitrogen flushing during the irradiation should be solutions almost oxygen free. In rigorously degassed solutions oxidation occurred during work-up, and this is presumed to be the case for solutions flushed with nitrogen.

Figure 1. Ultraviolet spectra of anthrol anion, ---; sodium 9-anthroate, . . . ; and the aqueous solution of sodium 9-anthroate after irradiation and before exposure to atmospheric oxygen, —.

length 290-360 m $\mu$  gave substantially lower yields of photodimer than were obtained when the full output of lamp above 290 m $\mu$  was used.<sup>10</sup> Irradiation of carefully degassed aqueous solutions of sodium 9-anthroate in sealed ampoules permitted isolation and characterization of carbon monoxide. Monitoring the irradiation of the degassed solutions in sealed ampoules by ultraviolet absorption spectroscopy revealed the presence of an intermediate with an absorption maximum at about 453 m $\mu$ . This absorption is characteristic of 9-anthrol anion (Figure 1).

Irradiation (290-360 m $\mu$ ) of the disodium salt of the photodimer in degassed solution in a sealed tube gave sodium 9-anthroate and the anthrol anion. The formation of dimer is thus photochemically reversible when light is absorbed by the dimer. Formation of anthrol anion presumably is a secondary process based on sodium 9-anthroate which has a greater molar extinction coefficient in this region than the dimer.

#### Discussion

The photochemical conversions of sodium 9-anthroate are summarized in Chart I. Formation of the photodimer is reversible, and this reversibility is presumably responsible for the wavelength dependence of dimer yield. Decarboxylation of sodium 9-anthroate is mildly surprising, but other photochemical decarboxylations are known.<sup>11</sup> In any event, decarboxylation is a minor process. The most interesting reaction is the photochemical conversion of 9-anthroate anion to anthrol anion. The anthrol anion is known to react rapidly with oxygen giving both anthraquinone and 10,10'-bianthrone.<sup>12</sup> In the absence of oxygen only anthrol anion is formed, but when oxygen is admitted during work-up it is oxidized to the observed products. The nature of the excitation ( $n, \pi^*$  or  $\pi, \pi^*$ ) in sodium 9-anthroate and the multiplicity of the reactive state are not known.

The formation of the anthrol anion can be described in much the same fashion as the nitro to nitrite rearrangements. It is assumed for the sake of discussion

(10) This wavelength dependence is analogous to that reported by Greene for 9-nitroanthracene.<sup>6</sup>

(11) J. D. Margcrum, *J. Am. Chem. Soc.*, 87, 3772 (1965).

that the excitation responsible for this reaction is localized in the carboxylate group and is  $n, \pi^*$ . The plane of the carboxylate group will be nearly at right angles to the plane of the aromatic rings because of the *peri* hydrogens.

The out-of-plane carboxylate group has the half-vacant nonbonding orbital properly aligned for interaction with the  $\pi$  system of the aromatic rings.<sup>13</sup> The anthrol anion formed by loss of carbon monoxide is stable (in the absence of oxygen), in contrast to the 9-anthryloxy radical which is formed when nitric oxide is lost from the corresponding nitrite.

## Experimental Section

**Irradiation of Sodium 9-Anthroate Open to the Atmosphere.** A water solution of sodium 9-anthroate was made by dissolving 9-anthroic acid (4.0 g, 0.018 mole) in water (450 ml) to which sodium hydroxide (18.0 ml of 1.00 M, 0.018 mole) had been added.

(13) The description of the excited state given above is very crude. Actually, the two nonbonding p atomic orbitals combine to give symmetric ( $n_s$ ) and antisymmetric ( $n_a$ ) combinations. The p atomic orbital representation is used for convenience.

The solution (0.040 M, pH 9.5) was filtered into a 500-ml capacity Pyrex immersion well. The solution, open to the atmosphere, was irradiated for 5 hr with a Hanovia Type A, medium-pressure, mercury arc lamp. The solution was filtered. The solid (56 mg, 1.4% of the sample weight, mp 234–237°) was dissolved in hot benzene and chromatographed on 40 g of silica gel giving anthraquinone (0.04 g, 1.1%, mp 255–262°). The filtrate from the irradiation was continuously extracted with ether giving anthraquinone (0.07 g, 1.8% yield). The total yield of anthraquinone was 2.9%.

The water solution was acidified with 1.5 ml of concentrated hydrochloric acid and continuously extracted with ether. White crystals formed in the yellow ether solution. Filtration yielded the photodimer of 9-anthroic acid (0.99 g, 25% yield, mp 216–220°, infrared 5.88  $\mu$ ).

*Anal.* Calcd for  $C_{20}H_{10}O_4$ : C, 81.07; H, 4.54. Found: C, 80.98; H, 4.63.

The acid dimer was converted to the methyl ester (mp 222–223°, lit.<sup>7</sup> 226–227°) by addition of the acid chloride to methanol. The mass spectrum of the methyl ester showed  $m/e$  472 (0.5% of base) for the parent ion and  $m/e$  236 (93.5% of base) for symmetrical cleavage of the dimer.

Evaporation of the ether solution gave crude 9-anthroic acid (23 g, 58%) which was identified by infrared comparison.

**Irradiation of Sodium 9-Anthroate with a Nitrogen Flush.** A water solution of sodium 9-anthroate was made from 9-anthroic acid (4.0 g, 0.018 mole) and sodium hydroxide (18 ml of 1.00 M, 0.018 mole) and enough water to make a total volume of 450 ml. The solution (0.040 M, pH 9) was filtered into a 500-ml capacity Pyrex well. Nitrogen was passed through the solution for 1 hr. The yellow solution was irradiated for 5 hr with a Hanovia Type A, medium-pressure, mercury arc lamp with a continuous flow of purified nitrogen. The solution was filtered. The solid (120 mg, 3.0% of the sample weight) was chromatographed on 50 g of silica gel giving anthraquinone (0.10 g, 2.7%, mp 232–238°, identified by infrared comparison with an authentic sample). The mass spectrum of the product showed  $m/e$  208 for the parent ion,  $m/e$  180 with a metastable ion at  $m/e$  155.5 for the loss of carbon monoxide, and  $m/e$  152 with a metastable ion at 128.2 for the second loss of carbon monoxide, in agreement with the mass spectrum of anthraquinone reported by Beynon.<sup>14</sup>

Continuous extraction of the filtrate with ether gave anthraquinone (0.03 g, 0.8%). The total yield of anthraquinone was 3.5%.

The water solution was acidified with 1.5 ml of concentrated hydrochloric acid and continuously extracted with ether. Filtration of the yellow ether solution gave the photodimer of 9-anthroic acid (1.5 g, 39% yield, mp 219–220°) which was identified by infrared comparison. Evaporation of the ether gave crude 9-anthroic acid (1.3 g, 33%).

**Irradiation of Sodium 9-Anthroate at Lower Concentrations.** The solution of sodium 9-anthroate was made from 9-anthroic acid (2.00 g, 0.009 mole), sodium hydroxide (20 ml of 0.50 M, 0.010 mole), and enough water to make the total volume 2 l. The solution (0.0045 M, pH 11) was filtered into a Pyrex immersion well, and purified nitrogen was passed through for 2 hr. The nitrogen was purified by passage through a trap, two bottles of Fieser's solution, two traps, 18 M sulfuric acid, a trap, and finally a drying tower. The solution was irradiated for 20 hr with a Hanovia Type A, medium-pressure, mercury arc lamp.

The solution was filtered. The solid (0.2 g, 16% of the sample weight) was chromatographed on 40 g of silica gel giving anthracene (0.06 g, 4%, 206–214°), anthraquinone (0.17 g, 9%, 225–235°,  $C=O$ , 5.97  $\mu$ ), and 10,10'-bianthrone (0.04 g, 2%, mp 243–247°,  $C=O$ , 6.02  $\mu$ ).

The filtrate from the irradiation was acidified with 1.5 ml of concentrated hydrochloric acid and continuously extracted with ether. Filtration of the yellow ether solution after concentration gave the photodimer of 9-anthroic acid (0.62 g, 31% yield, mp 215–219°). Evaporation of the ether solution gave 9-anthroic acid (0.84 g, 42% yield, mp 212–214°).

**Irradiation of Sodium 9-Anthroate with a Filter Solution.** The filter solution was made by dissolving nickel sulfate (690 g of  $NiSO_4 \cdot 6H_2O$ ) and cobalt sulfate (220 g of  $CoSO_4 \cdot 7H_2O$ ) in water (1 l.). This solution for a 0.8-cm path length transmits 90% of the light at 300 m $\mu$  and less than 2.0% of the light from 360 to 540 m $\mu$ .

The solution of sodium 9-anthroate was made from 9-anthroic acid (2.4 g, 0.0108 mole), sodium hydroxide (1.00 g, 0.025 mole), and

(14) J. H. Beynon, G. R. Lester, and A. E. Williams, *J. Phys. Chem.*, **63**, 1861 (1959).

water to make a total volume of 3.2 l. The solution ( $M$ ,  $pH > 11$ ) was filtered into a Pyrex immersion well. Nitrogen was passed through for 1.5 hr. The solution was irradiated for 19.5 hr with a Hanovia Type A, medium-pressure, mercury arc lamp. The highest temperature filter solution reached was  $55^\circ$ . The solution was filtered. 1 (0.28 g, 12% of the sample weight) was chromatographed of silica gel giving anthracene (0.02 g, 1%, mp  $196-203^\circ$ ), anthraquinone (0.15 g, 6.7%, mp  $230-239^\circ$ ), and 10,10'-bianthrone (1.2%, mp  $253-256^\circ$ ).

Filtrate was continuously extracted with ether for 3 days. Ether (0.2 g) from the evaporation of the ether was chromatographed on 20 g of silica gel giving anthracene (0.03 g, 1.5%, mp  $^\circ$ ), anthraquinone (0.09 g, 4.0%, mp  $232-243^\circ$ ), and crude bianthrone (0.05 g, 2.4%, mp  $235-240^\circ$ ). The total yields of three products were anthracene (2.5%), anthraquinone (6.6%), and 10,10'-bianthrone (6.6%).

Filtrate was acidified with 10 ml of concentrated hydrochloric acid and continuously extracted with ether for 3 days. The ether was evaporated to dryness. The solid was recrystallized from benzene. Filtration of the hot benzene solution gave the mother liquor of 9-anthroic acid (0.25 g, 11%). Upon cooling, the solution gave crystals of 9-anthroic acid (1.4 g, 54%).

**Irradiation of Sodium 9-Anthroate in a Sealed Tube.** The ampoule was made from a test tube ( $13 \times 100$  mm) and a standard ground glass joint (14/20). The ampoule was filled with 5 ml of sodium 9-anthroate (0.003  $M$ ) in water. The ampoule was frozen in an ice-trichloroethylene bath, evacuated to 0.025 mm, closed, and allowed to thaw. This process was repeated except before sealing the second time it was sealed off. The ampoule was irradiated for 5 hr with a Hanovia Type A, medium-pressure, mercury arc lamp using the nickel sulfate-cobalt sulfate filter described above. The ultraviolet spectrum (Figure 1) shows the presence of the anthrol anion.

**Irradiation of Sodium 9-Anthroate in a Sealed Tube to Identify Carbon Monoxide.** 9-Anthroic acid (2.00 g, 0.009 mole) and 10% sodium hydroxide (50 ml) were diluted to 75 ml. The solution (0.12  $M$ ) was put in a heavy-walled, Pyrex, 100-ml capacity tube fitted with a vacuum stopcock. The tube was frozen, evacuated to 0.02 mm, closed, and thawed. This process was repeated four times. The tube was irradiated for 19 hr with a Hanovia Type A, medium-pressure, mercury arc lamp using the nickel sulfate-cobalt sulfate filter solution described above. After irradiation the product gases were expanded into an infrared gas cell. The infrared spectrum showed, in addition to the bands for the water present, a broad band at  $4.7 \mu$  (lit.<sup>18</sup> for carbon monoxide  $4.67 \mu$ ).

The solution was filtered giving a solid (0.02 g) which by infrared comparison was shown to be a mixture of anthraquinone and 10,10'-bianthrone. No further attempt at separation was made.

**Irradiation of the Disodium Salt of the Photodimer of 9-Anthroic Acid in a Sealed Tube.** The dimer of 9-anthroic acid (0.222 g, 0.0005 mole) was dissolved in 10% sodium hydroxide (20 ml) and diluted to 25 ml (0.02  $M$ ). An ampoule containing 6 ml of the solution was prepared in the manner previously described and irradiated. The ultraviolet spectrum of the solution showed the presence of sodium 9-anthroate and the anthrol anion. Filtration of the solution gave water-insoluble compounds (0.006 g, 11% of starting material). The filtrate was acidified and continuously extracted with ether. Filtration of the ether solution gave dimer (0.038 g, 71% yield) and evaporation gave 9-anthroic acid (0.007 g, 13% yield).

## The Photorearrangement of 2,3-Dihydropyrazines

Peter Beak and John L. Miesel<sup>1</sup>

Contribution from the W. A. Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois. Received November 28, 1966

**Abstract:** Six 2,3-dihydropyrazines have been found to rearrange to imidazoles upon photolysis. Data are presented in support of the proposal that the reaction proceeds through an irreversibly formed enediimine intermediate.

Anal comparison of the photolysis of the 2,3-dihydropyrazine system 1 with the photochemistry structurally related and extensively studied  $\alpha$ -acyl systems 2 and six-membered cyclic dienes 3 of practical and theoretical interest.<sup>2</sup> Analogy

suggests 1,4<sup>3</sup> and 1,2<sup>4</sup> additions, reduction,<sup>5</sup> oxida-

tional Science Foundation Fellow, 1962-1964; University of Illinois, 1964-1965; Union Carbide Fellow, 1965-1966.

The formal aspects of these comparisons must be emphasized. The systems are involved and the details of the processes may be different. Cf. J. G. Calvert and J. N. Pitts, "Photochemistry," John Wiley and Sons, Inc., New York, N. Y., 1966, pp 528-530.

be expected from the irradiation of 1. Previous study of the photochemistry of imines has shown this functional group resembles the carbonyl group in its photo-reactions of reduction,<sup>12</sup> addition,<sup>13</sup> and prototropy.<sup>14</sup> On the other hand photoisomerization of anils,<sup>15</sup> novel photoaddition and cyclization reactions,<sup>16</sup> and photo-oxidation<sup>17</sup> have been observed for the imine function. Pyrazine, a heteroaromatic imine, has been reported to photoisomerize to pyrimidine<sup>18a</sup> and to undergo photo-fragmentation to acetylene and hydrogen cyanide.<sup>18b</sup> Many of the possibilities suggested for the 2,3-dihydropyrazines by these analogies are intriguing. This synthetic potential and an interest in the chemical consequences of  $n \rightarrow \pi^*$  excitation of diunsaturated system constrained to a six-membered ring<sup>19</sup> prompted this study.

In this paper we report a new reaction, the photo-rearrangement of 2,3-dihydropyrazines to imidazoles.<sup>20</sup> Evidence is presented which suggests an enediimine, formed irreversibly after  $n \rightarrow \pi^*$  excitation, is an intermediate in this reaction.

## Results and Discussion

**Spectral Properties.** The low-intensity  $n \rightarrow \pi^*$  bands expected for a dihydropyrazine<sup>21</sup> could not be resolved for 2,3-dihydro-5,6-dimethylpyrazine (4) or 2,3-dihydro-5,6-diphenylpyrazine (5). These absorptions appear as the longest wavelength band in each

4

5

case with a broad featureless structure. By the empirical criteria of low intensity, absence of absorptions in the hydrocarbon analogs, and the shift of the absorption to shorter wavelengths in hydrogen-bonding solvents (Table I), this absorption is clearly of the  $n \rightarrow \pi^*$  type.<sup>19,21,22</sup> Attempts to demonstrate the disappearance of the long-wavelength band in acid were precluded by the instability of the compounds under these conditions.

**Table I.** The  $n \rightarrow \pi^*$  Absorptions of 2,3-Dihydro-5,6-dimethylpyrazine (4) and 2,3-Dihydro-5,6-diphenylpyrazine (5)

Compound	Solvent	$\lambda_{\max}$ , $m\mu$	$\epsilon$

Arnold has independently discovered this reaction; D. R. Arnold, personal communication. We wish to thank Dr. Arnold for this information and for valuable discussion of this manuscript.

(21) Analogous absorptions in related molecules are of low intensity although allowed by local symmetry and affected by molecular symmetry; (a) for a general discussion see J. W. Sidman, *Chem. Rev.*, 58, 689 (1958); M. Kasha, *Discussions Faraday Soc.*, 9, 14 (1950); (b) for an example see K. K. Innes, J. D. Simons, and S. G. Tilford, *J. Mol. Spectry.*, 11, 257 (1963).

In the ultraviolet spectrum of 4 the  $n \rightarrow \pi^*$  band is the only absorption above 290  $m\mu$ ; in the case of 5 there is a tailing absorption from 290 to 310  $m\mu$  from an absorption shoulder at 280  $m\mu$ . Accordingly the use of a Pyrex filter in photochemical experiments would allow only excitation of the  $n \rightarrow \pi^*$  band for 4 and mainly  $n \rightarrow \pi^*$  excitation for 5. 2,3-Dihydro-5,6-diphenylpyrazine (5) did not show fluorescence in methanol at room temperature or phosphorescence in an ethanol-glycerol glass at 77°K.

**Photolyses.** Irradiation of 2,3-dihydro-5,6-dimethylpyrazine (4) in absolute ethanol using a 450-w high-pressure mercury resonance lamp with a Pyrex filter<sup>21</sup> for 5 hr yields 71% 1,4,5-trimethylimidazole (6).

The product was identified by spectral comparison with an authentic sample and by preparation of the picrate.

Photolysis of 2,3-dihydro-5,6-diphenylpyrazine gives 4,5-diphenyl-1-methylimidazole (7) in 75% yield. In some photolyses 4,5-diphenyl-1-ethoxymethylimidazole (8) may also be isolated in about 10% yield. The major product was identified as 7 by spectral and melting point comparisons with an authentic sample. The structure of 8 is based on analytical, infrared, ultra-

(22) The short-wavelength shift caused by conjugative substituents for the  $n \rightarrow \pi^*$  band of carbonyl groups<sup>21a</sup> appears to be altogether reversed in comparing the  $n \rightarrow \pi^*$  absorptions of 4 with 5. The reliability of this correlation for imines is somewhat compromised by its failure to predict the "conjugative" shifts of the  $n \rightarrow \pi^*$  absorptions of azo compounds: H. H. Jaffé and M. Orchin, "Theory and Applications of Ultraviolet Spectroscopy," John Wiley and Sons, Inc., New York, N. Y., 1962, pp 185, 430.

(23) In the following discussion these conditions should be presumed unless otherwise stated.

nmr, and mass spectral data as well as its conversion to 4,5-diphenylimidazole (9) in 70% yield on treatment with refluxing hydriodic acid. The quantum yield for the disappearance of 2,3-dihydro-5,6-diphenylpyrazine (5) and the appearance of 4,5-diphenyl-

ylimidazole (7) are about 0.1. Photolyses of 5 in benzene<sup>25</sup> or in absolute ethanol using a 23-watt pressure mercury resonance lamp for 3 to 6 hr gave 7 in yields ranging from 70 to 90%. The use of ethanol as a solvent for 5 with the high-pressure lamp and a Pyrex filter gives 7 (4%), 8 (8%), and 9

effect this reaction provides a method for the transfer of substituents from the 2 and 3 positions of a dihydropyrazine to the 2 position and the exocyclic carbon bonded to nitrogen of an N-substituted imidazole. The availability of 2,3-dihydropyrazines from diamine precursors suggests the reaction for some synthetic convenience over present procedures for the preparation of substituted imidazoles. The synthetic potential and the variation in products obtained in the reaction may be illustrated by the photolysis of *trans*-2,3-diphenyl-5,6,7,8,9,10-hexahydroalaline (10). In absolute ethanol the prod-

ucts were 2,3-diphenyl-6,7,8,9-tetrahydro-5H-imidazopyrazine (11) in 9% yield and 2,3-diphenyl-5,6,7,8,9-tetrahydro-5H-imidazo[1,2-a]azepine (12) in 8% yield. In cyclohexane 11 was produced in 8% yield and 2,3-diphenyl-8,9-dihydro-7H-imidazo[1,2-a]azepine (13) in 19% yield. The structural assignments were based on analytical data, consistency of ultraviolet, infrared, nmr, and mass spectral data with the expected products using 7 and 8 as model compounds, and the con-

sequently this reaction complements the conversion of 5 to 4,5-diphenylimidazole with hydrogen peroxide: H. I. X. Mager and W. Rec. Trav. Chim., 84, 314 (1965).

version of 13 to 11 on catalytic hydrogenation. This appears to be the second synthesis of this type of imidazopyrazine ring system.<sup>26</sup>

Additional cases are provided by photolyses of 2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine (14), 2,3-dihydro-2-methyl-5,6-diphenylpyrazine (15), and 2,3-dihydro-2-isobutyl-5,6-diphenylpyrazine (16). Irradiation of an ethanolic solution of 14<sup>26</sup> for 10 min gave 4,5-diphenyl-1-(1-ethoxyethyl)-2-methylimidazole (17) in 55% yield.<sup>27</sup> Reaction of 15 under these conditions for 8 hr gave 1,2-dimethyl-4,5-diphenylimidazole (18) (42%) and an unresolved mixture of 4,5-diphenyl-1-ethoxymethyl-2-methylimidazole (19) and 4,5-diphenyl-1-(1-ethoxyethyl)imidazole (20) (20%). Photolysis of 16 for 10 min gave 2-isobutyl-4,5-diphenyl-1-methylimidazole (21) (50%)<sup>27</sup> as well as material characterized by its spectral properties as 2-isobutyl-4,5-diphenyl-1-ethoxymethylimidazole (22) (6%)<sup>27</sup> and 1-(1-ethoxy-3-methylbutyl)-4,5-diphenylimidazole (23) (20%).<sup>27</sup> Conversion of 17 to 4,5-diphenyl-2-methylimidazole was achieved with hydriodic acid while 18 was identified by direct comparison with an authentic sample.

Irradiation of 2,3-dihydro-2-isobutyl-5,6-diphenylpyrazine (16) in cyclohexane took an unexpected course and produced 1,2-di(2-isobutyl-4,5-diphenylimidazoylethane (24) (43%) in addition to the expected product 21 (26%). The infrared and ultraviolet spectra of this compound are very similar to that of 21, but the extinction coefficient in the ultraviolet was approximately

twice that of 21. The singlet assigned to the N-substituted methylene protons of 24 appears at  $\delta$  3.78 and this value compares well with the chemical shift of  $\delta$  3.30 for the N-methyl group in 21 and of  $\delta$  3.94 for the methylene of the N-ethyl group in 4,5-diphenyl-1-ethylimidazole. The mass spectrum of 24 confirmed the

(25) R. G. Glushov and O. Y. Mayidson, Dokl. Akad. Nauk SSSR, 133, 585 (1960).

(26) The *cis* isomer and a mixture of *cis* and *trans* isomers gave the same product in separate experiments.

(27) This is based on starting material consumed.

molecular weight of 578 and gave major fragments at  $m/e$  303 (metastable for  $578 \rightarrow 303$  observed at 158.5; calcd, 159) and 289, consistent with species a and b which can be envisioned to arise from 24.

**Intermediates.** These conversions of 2,3-dihydropyrazines to imidazoles may be formulated for the general case as proceeding *via* an enediimine 25 formed by photolytic ring opening. Subsequent ring closure of 25 to 26 would generate an intermediate which could lead to an N-alkylimidazole (27) by proton transfer or to an N-ethoxyalkylimidazole (29a) by addition

of ethanol followed by oxidation<sup>28</sup> of the resulting imidazoline 28.

The generality of the photochemical ring opening reactions for systems isoelectronic with 1,3-cyclohexadienes was predicted by Barton 8 years ago.<sup>7a</sup> Despite the formidable uncertainties involved in drawing formal analogies for photochemical reactions,<sup>2,29</sup> the present case can be considered to support the empirical utility of Barton's prediction. The cyclization of 25 to 26 as a nonphotochemical reaction has reasonable precedent.<sup>30</sup>

This proposal outlines the general nature of the intermediates, and the involvement of different tautomers and timing of the reactions are open to discussion. At least two species, 30 and 31, which could fulfill the function of 25, can be envisioned. Analogy<sup>2,29</sup> clearly favors 25, however, and for the lack of definitive

information about the alternatives, 25 will be provisionally preferred.<sup>31</sup>

(28) The facility of the proposed reaction is suggested by the ready oxidation of aryl-2-imidazolines: K. Hoffmann, "Imidazole and Its Derivatives," Part 1, Interscience Publishers, Inc., New York, N. Y., 1953, p 42. The oxidation could be a photoreaction due to traces of unremoved oxygen in the nitrogen used for purging or a subsequent reaction occurring in the work-up. M. Busch, *Ber.*, **64**, 1816 (1931), claims the preparation of a 4-imidazoline bearing hydrogens on both nitrogen atoms and reports this compound is readily oxidized to the corresponding imidazole.

(29) See the discussion by F. B. Mallory, C. S. Wood, and J. T. Gordon, *J. Am. Chem. Soc.*, **86**, 3094 (1964), for a cautionary note on the use of analogy for photochemical processes.

(30) G. McCoy and A. Day, *ibid.*, **65**, 2159 (1943).

The results of the photolyses of 10 can be accommodated in the proposed mechanistic framework. Production of 2,3-diphenyl-8,9-dihydro-6H-imidazo[1,2-a]azepine (13) from 10 under these conditions could occur by proton transfer of 32 to give 33 followed by oxidation.

The formation of 4,5-diphenylimidazole (9) in the photolysis of 2,3-dihydro-5,6-diphenylpyrazine (5) in 95% ethanol could result from the loss of the elements of formaldehyde from 28b or 29b formed by addition of water to 26 or by exchange with the corresponding ethers.

The product distributions in the cases of the unsymmetrically 2,3-substituted 2,3-dihydropyrazines 15 and 16 can be rationalized if the intermediates corresponding to 25 and 26 are considered to lead predominantly to imidazole products resulting from intramolecular nucleophilic addition at the most substituted imine carbon atom.<sup>32</sup> For example, 1,2-dimethyl-4,5-diphenylimidazole (18) is formed in the photolysis of 2,3-dihydro-2-methyl-5,6-diphenylpyrazine (15) rather than 1-ethyl-4,5-diphenylimidazole.

The formation of 1,2-di(2-isobutyl-4,5-diphenylimidazolyl)ethane (24) on photolysis of 16 in cyclohexane may result from the condensation of two molecules of 34 to give 35, a species which could undergo ring closure and proton transfer to yield 37, followed by oxidation. Tautomeric variants of this scheme can be envisioned. A different possibility is photoreaction of 34 to form the diazetidine 36 followed by ring closure,

(31) The assumption that changes in bond orders or overlap populations on transformation from the ground to the excited state indicate positions of bond formation and bond breaking in the excited state<sup>32a</sup> may be applied to the present case by use of the extended Hückel method.<sup>32b</sup> In agreement with the suggested intermediacy of the enediimine 25, bond overlap populations obtained from the calculations show a bond weakening of the 2,3 and 1,6 bonds and a bond strengthening of the 1,2 and 5,6 bonds on promotion of an electron from the highest occupied to the lowest unoccupied orbital of 2,3-dihydropyrazine (1). In contrast to this a strengthening of the 2,3 bond is obtained on promotion of an electron from the second highest occupied to the lowest unoccupied orbital of 1.

Phys.*, **39**, 1397 (1963); the program used was kindly provided by Mr. Donald Dugre. We are grateful to Mr. Dugre and Professor Hoffmann for use of the program and for advice.

(33) Although rationales can be constructed for this proposal, the limited data, as well as the fact that small energy differences of subtle origin may be involved, suggest that further speculation is not warranted.

ring opening, and proton transfer to give 37. The intermediacy of 36 is suggested by analogy to the proposals of Searles and Clasen for the photolytic conversion of anils to stilbenes and azobenzenes.<sup>16c</sup> These rationales, however, do not explain the apparently anomalous formation of 24.

Support for the proposed intermediates is provided by the deuterium incorporation observed in the course of photolysis. Irradiation of 5 in ethanol-*d* (95% *d*), followed by heating the products in ethanol-*d* to complete the exchange of the labile imidazole C-2 proton, gave 4,5-diphenyl-1-methyl-*d*-imidazole-2-*d* (38) which has a minimum of 90% dideuterium incorporation. The extent of deuterium incorporation was determined by mass spectrometry, and the position of deuteration was determined by nmr analysis. Direct comparison of the spectrum of 38 with that of 7 showed the expected ratio, 10:2, of proton resonances, and the signal for the N-deuteriomethyl group at  $\delta$  3.42 had an unresolved triplet shape.<sup>34</sup> Isolation of unreacted 5 demonstrated that it did not exchange under the conditions of the experiment, while control experiments with 4,5-diphenyl-1-methylimidazole (7) showed that exchange of only the C-2 proton occurred on treatment with ethanol-*d* under

the photolysis conditions.<sup>35</sup> The incorporation of deu-

(34) The hydrogen-deuterium coupling constant would be expected to be on the order of 1–2 cps.

(35) H. A. Staab, M. Th. Wu, A. Mannschreck, and G. Schwalbach, *Tetrahedron Letters*, 845 (1964); T. M. Harris and J. L. Randall, *Chem. Ind. (London)*, 1728 (1965); R. O. Olofson, private communication.

terium into the N-methyl group of the product imidazole is expected for an intermediate corresponding to 26 in this reaction.

In an attempt to generate a relatively stable enediimine, the irradiation of 2,3-dihydro-5,6-diphenyl-2,2,3,3-tetramethylpyrazine (39) was investigated. The expected enediimine intermediate in this case would not be capable of imidazole formation by the prescribed pathway. Photolysis of 39 in absolute ethanol for 2.5 hr gave 2,2-dimethyl-4,5-diphenyl-3-imidazoline (40) (60%) and 2,2-dimethyl-4,5-diphenylisimidazole (41) (9%). The imidazoline 40 was identified by

analytical, infrared, ultraviolet, nmr, and mass spectral data. The ultraviolet spectrum of 40,  $\lambda_{\text{max}}$  245 m $\mu$  ( $\epsilon$  12,500), is characteristic of phenyl-substituted Schiff bases.<sup>36</sup> The nmr resonances of two methyl groups at  $\delta$  1.62 and 1.48 are consistent with the assigned structure and indicate that alternative structures bearing methyl groups on a carbon doubly bonded to nitrogen can be ruled out.<sup>37</sup> The mass spectrum shows that losses of hydrogen, a methyl group, and benzonitrile from the molecular ion, as expected for 40, are favorable processes. Chemical confirmation of this assignment was provided by the oxidation of 40 to 41 with sulfur at 125° in high yield and by the hydrolysis of 40 to desyl-

amine (42) by dilute acid. The structure of 41 was established by spectral and physical comparison with an authentic sample.

Although detection of the presumed intermediate 43 has not been possible,<sup>38</sup> the observed products are consistent with its transient existence. Ring closure

of 43 followed by loss of the nitrogen substituent, presumably with formation of acetone or acetone diethyl ketal, would lead to 40. The formation of 2,2-di-

(36) G. E. McCasland and E. C. Horswill, *J. Am. Chem. Soc.*, 73, 3923 (1951).

(37) E. Arnal, J. Elyuero, R. Jacquier, C. Marzin, and J. Wylde, *Bull. Soc. Chim. France*, 877 (1965).

(38) A number of experiments, under a variety of conditions, were carried out and attempts were made to detect 43 as a nonisolable species.

methyl-4,5-diphenylisimidazole (41) in this reaction may be due to photooxidation of 40 by minor products or impurities in the system.

If the photolytic conversion of the 2,3-dihydropyrazines to imidazoles proceeds *via* an enediimine corresponding to 25, there is a reasonable possibility that the photochemical ring opening is reversible, *i.e.*, that the enediimine can re-form a 2,3-dihydropyrazine.<sup>39</sup> In principle, this process could be detected by partial photolysis of a 2,3-dihydropyrazine which is optically active by virtue of an asymmetric center at position 2 and isolation of the starting material to determine if racemization, requisite in ring closure of the planar enediimine intermediate, has occurred. Photolysis of optically active 2,3-dihydro-2-isobutyl-5,6-diphenylpyrazine (16) for 10 min in absolute ethanol or cyclohexane followed by recovery of starting material in 55 and 44% yields showed that less than 5% racemization had occurred. Accordingly, the photochemical ring opening is not reversible within the limits of detection.<sup>40</sup>

**Excited Species.** On the basis of the spectral data for 4 the reaction may be formulated as occurring after  $n \rightarrow \pi^*$  excitation. The photolysis of 2,3-dihydro-2,3-diphenylpyrazine (5) to give 4,5-diphenyl-1-methylimidazole (7) does not appear to be sensitized or quenched by benzophenone,<sup>41</sup> triphenylene,<sup>41</sup> *trans*-stilbene,<sup>42</sup> naphthalene, or perylene, even when the latter is the reaction solvent. These results suggest, but do not require, that a triplet species is not an intermediate in the conversion of 5 to 7.<sup>43</sup> The reaction may provisionally be formulated as occurring in an  $n, \pi^*$  singlet. It is possible that a triplet which lies less than *ca.* 60 kcal/mole above its ground state could be in-

volved as could a triplet which is inefficient in energy transfer. Observation of the phosphorescence spectrum of 4 and 5 in conjunction with a quantitative study of quenching and sensitization could settle this point. Investigation of the nature of the  $n \rightarrow \pi^*$  absorptions of 4 and 5 would also be of interest for a further understanding of these reactions.

## Experimental Section<sup>44,45</sup>

**2,3-Dihydro-5,6-dimethylpyrazine (4)** was prepared by the method of Ishiguro and Matsumura<sup>47</sup> bp 60–62° (18 mm) (lit.<sup>47</sup> 60–63° (18 mm)),  $n_D^{20}$  1.4826. The nmr spectrum consists of singlets at  $\delta$  3.28 (relative area 2),  $\text{CH}_3$ , and 2.10 (relative area 3),  $\text{C-CH}_3$ . The infrared and ultraviolet ( $\lambda_{\text{max}}$  230 ( $\epsilon$  1740) and 337  $\text{m}\mu$  ( $\epsilon$  200)) are consistent with the established structure. 2,3-Dihydro-5,6-dimethylpyrazine is unstable to standing in air but is stable for several weeks if stored under nitrogen in the refrigerator.

*Anal.* Calcd for  $\text{C}_6\text{H}_{12}\text{N}_2$ : C, 65.42; H, 9.15; N, 25.43. Found C, 65.24; H, 9.07; N, 25.35.

**2,3-Dihydro-5,6-diphenylpyrazine (5)** was prepared according to Amundsen,<sup>48</sup> mp 162.5–163.5° (lit.<sup>48</sup> 161.5–162.5°). The nmr spectrum consists of an unsymmetrical multiplet centered at  $\delta$  7.3 (relative area 5),  $\text{Ar-H}$ , and a singlet at  $\delta$  3.7 (relative area 2),  $\text{CH}_3$ . The infrared and ultraviolet ( $\lambda_{\text{max}}$  224 ( $\epsilon$  15,100), 288 ( $\epsilon$  5740), and 363.5  $\text{m}\mu$  ( $\epsilon$  440)) are consistent with the established structure. The mass spectrum showed major fragment peaks at  $m/e$  131 and 103 corresponding to the loss of the elements of benzonitrile. No fluorescence of 2,3-dihydro-5,6-diphenylpyrazine was observed in methanol solution at room temperature under conditions such that a fluorescence quantum yield of 0.01 would have been detected. No phosphorescence of 5 in a 1:1 ethanol–glycerol glass at 77°K was observed.

***trans*-2,3-Diphenyl-5,6,7,8,9,10-hexahydroquinoxaline (10).** To a solution of 2.9 g of benzil in 10 ml of absolute ethanol was added 2.18 g of *trans*-1,2-diaminocyclohexane- $\text{CO}_2$  adduct in 5 ml of absolute ethanol. The solution was heated at reflux on a steam bath under a positive pressure of nitrogen for 45 min. After 5–10 min, yellow plates precipitated. The reaction mixture was cooled in ice and filtered, and the solid collected was washed with portions of cold 95% ethanol. The product consisted of 3.82 g of yellow plates, mp 170.5–173° (lit.<sup>49</sup> 167–168°). The product was sublimed at 110° (0.1 mm) to give yellow needles, mp 171–172°. The nmr spectrum consisted of a multiplet at  $\delta$  7.24 (relative area 10),  $\text{ArH}$ , a series of multiplets at 1.20–3.00 (relative area 10),  $\text{C-H}$ . The infrared, mass (molecular ion at  $m/e$  288), and ultraviolet spectra ( $\lambda_{\text{max}}$  223 ( $\epsilon$  15,000), 260 ( $\epsilon$  5100), 290 ( $\epsilon$  5300), and 369  $\text{m}\mu$  ( $\epsilon$  450)) were consistent with the expected values.

*Anal.* Calcd for  $\text{C}_{20}\text{H}_{20}\text{N}_2$ : C, 83.29; H, 6.99; N, 9.71; mol wt, 288. Found: C, 83.26; H, 7.04; N, 9.33; mol wt, 280 (benzene).

***cis*-2,3-Dihydro-2,3-dimethyl-5,6-diphenylpyrazine (14).** *meso*-2,3-Diaminobutane was isolated from commercial 2,3-diaminobutane by the method of Dickey, Fickett, and Lucas.<sup>46</sup> A solu-

(44) The melting points were determined with a Thomas-Hoover capillary apparatus and are corrected. The boiling points are uncorrected. The infrared spectra were determined on a Perkin-Elmer Model 521 infrared spectrometer using 10% chloroform solutions, unless otherwise noted. The ultraviolet spectra were measured on a Cary Model 14 M spectrophotometer and a Perkin-Elmer 202 ultraviolet-visible spectrometer using 95% ethanol solutions unless otherwise noted. The proton magnetic resonance spectra were obtained on a Varian Associates A-60 spectrometer using 10–30% chloroform- $d$  solutions, unless otherwise noted, and are reported in  $\delta$  (parts per million) relative to the internal standard, tetramethylsilane. The mass spectra were determined by Mr. J. Wrona on an Atlas CH4 mass spectrometer. Optical rotation measurements were performed on a Zeiss 0.01° polarimeter. Phosphorescence studies were performed using an Aminco-Bowman spectrofluorometer converted for phosphorescence. The fluorescence spectrum was taken on the instrument described by Weber and Bablovzian.<sup>44</sup>

(45) G. Weber and B. Bablovzian, *J. Biol. Chem.*, **241**, 2558 (1966).

(46) The microanalyses were performed by Mr. Joseph Nemeth and associates.

(47) T. Ishiguro and M. Matsumura, *Yakugaku Zasshi*, **78**, 229 (1958); *Chem. Abstr.*, **54**, 11862 (1958).

(48) L. Amundsen, *J. Chem. Educ.*, **16**, 567 (1939).

(49) A. Einhorn and B. Bull, *Ann.*, **295**, 209 (1897).

(50) F. Dickey, W. Fickett, and H. Lucas, *J. Am. Chem. Soc.*, **74**, 944 (1952).

(39) A number of analogies for such a process may be found in the photochemistry of 1,3,5-hexatrienes. For examples, see ref 7b; R. Srinivasan, *J. Am. Chem. Soc.*, **83**, 2806 (1961); G. J. Fonken, *Tetrahedron Letters*, 549 (1962).

(40) Application of the Woodward-Hoffmann concepts to the two  $n \rightarrow \pi^*$  states presumed for these purposes to be involved in the interconversion of a 2,3-disubstituted dihydropyrazine and its isomeric enediimine reveals that concerted ring opening and ring closure are allowed both as conrotatory and disrotatory processes: R. B. Woodward and R. Hoffmann, *J. Am. Chem. Soc.*, **87**, 395 (1965); H. Longuet-Higgins and E. W. Abrahamson, *ibid.*, **87**, 2045 (1965). In this case, unlike that of 1,3 cyclohexadienes, the symmetry rules allow a photolytic interconversion of *cis*- and *trans*-2,3-dihydro-2,3-disubstituted pyrazines by concerted processes. Experimental demonstration of this would assume both transitions occur, the enediimine to be photostable, and photochemical ring closure of the presumed enediimine intermediate. The latter reaction was not detectable with 16. Consistent with these results, no racemization of optically active 14 or photochemical interconversion of *cis* and *trans* isomers of 14 was found in incomplete reactions.

(41) Quantitative studies were complicated by competitive absorptions.

(42) The conversion of 5 to 7 in the presence of *trans*-stilbene provides a marked contrast to the photoaddition of *o*-quinones to *trans*-stilbene *via* a triplet species.<sup>3</sup>

staining 199 mg of *meso*-2,3-diaminobutane in benzene to a solution of 445 mg of benzil (94% of theoretical) in absolute ethanol. The solution was heated at reflux under a pressure of nitrogen for 2 hr. A total of 440 mg of fine, yellow crystals precipitated on cooling and scratching the solution. Second and third crops totaling 103 mg were obtained by concentrating the mother liquors.

Combined crude products were chromatographed on a column of 20 g of silica gel. Elution with 25% benzene-Skelly B gave unreacted benzil. Elution with 25% ether-benzene gave 2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine (14). The solid melted at 90–100° (0.15 mm) to give 400 mg of yellow needles, mp 98.5°. The nmr consisted of a multiplet at  $\delta$  7.38 (relative area 5), *ArH*, a quartet at 3.92 (relative area 1,  $J = 6$  cps),  $N=CHN$ , and a doublet at 1.26 (relative area 3,  $J = 6$  cps). The infrared and ultraviolet ( $\lambda_{\max}$  224 ( $\epsilon$  14,850), 290 ( $\epsilon$  5700), and 375 ( $\epsilon$  10)) spectra were consistent with the assigned structure.

Calcd for  $C_{20}H_{18}N_2$ : C, 82.40; H, 6.92; N, 10.68; 262. Found: C, 82.56; H, 6.96; N, 10.91; mol wt, 270. Partially resolved mixture of *cis*- and *trans*-2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazines (15) was also prepared. Racemic 2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine was resolved using *d*-tartaric acid following the method of Dickey, Fickett, and Lucas.<sup>50</sup> A tartrate salt of conical rotation of +0.90° was obtained and decomposed in aqueous sodium hydroxide. The amine was isolated by extraction of the aqueous solution with benzene.

A solution of 1.35 g of benzil (90% of theoretical) in 5 ml of absolute ethanol was added to a benzene solution containing 625 mg of 2,3-dihydro-2,3-diaminobutane by titration. The reaction mixture was purified as above.

Crystallization gave light yellow needles, mp 88–94°. The solid was ground with a mortar and pestle to ensure sample homogeneity. The nmr spectrum showed two different  $C-CH_3$  signals at  $\delta$  1.24 and 1.48 and was consistent with a mixture of *cis*- and *trans*-2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazines containing 26% *trans* isomer.

Optical rotation was determined using a solution of 219 mg of 2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine in 10 ml of 95% ethanol gave  $[\alpha]_D^{25} = 0.03^\circ$ ,  $[\alpha]_D^{25} = -28.7 \pm 4.75^\circ$ .

2,3-Dihydro-5,6-diphenyl-2-methylpyrazine (15) was prepared by the method of Strache,<sup>51</sup> mp 116–118° (lit.<sup>51</sup> 111–112°). The nmr spectrum consisted of a multiplet at  $\delta$  7.28 (relative area 10), *ArH*, 4.20–2.84 (relative area 3),  $N=CHN$ , and a doublet at 1.44 (relative area 3),  $C-CH_3$ , and ultraviolet spectra were consistent with the established structure.

2,3-Dihydro-2,3-dimethyl-5,6-diphenylpyrazine (16). To a solution of 1.84 g of benzil in 5 ml of absolute ethanol was added 1.07 g of 2,3-diamino-4-methylpentane.<sup>52</sup> The mixture was heated at reflux under a positive pressure of nitrogen for 2.5 hr. After sufficient to clarify the solution was added, the solution was cooled by ice and precipitation occurred. A total of 1.84 g (73%) of light yellow crystals, mp 66–69°, was collected by filtration. Crude product was chromatographed on silica gel. Elution with 25% ether-benzene gave a yellow oil which crystallized on cooling to light yellow needles, mp 68–70°. This solid was sublimed at 60° (0.12 mm) to give light yellow needles, mp 69–71°. The nmr spectrum consisted of a multiplet centered at  $\delta$  7.28 (relative area 10), *ArH*, a multiplet centered at 4.00 (relative area 1),  $N=CHN$ , multiplets centered at 3.26 (relative area 2),  $NCH_2$ , a series of multiplets at 1.30–2.20 (relative area 3),  $-CH_2CH-$ , and a doublet at 1.44 (relative area 6),  $-CH_3$ .

The infrared spectrum had strong absorptions at 2970, 1510, and 1400  $cm^{-1}$ . The ultraviolet spectrum ( $\lambda_{\max}$  224 ( $\epsilon$  15,450), 288 ( $\epsilon$  10,000), and 369  $m\mu$  ( $\epsilon$  440)) and the mass spectrum were consistent with the structure assigned. The optical rotation was determined using a solution of 231 mg of sublimed material in 10 ml of 95% ethanol gave  $[\alpha]_D^{25} = 0.07^\circ$ ,  $[\alpha]_D^{25} = 91.90 \pm 3.3^\circ$ .

Calcd for  $C_{20}H_{18}N_2$ : C, 82.72; H, 7.64; N, 9.65; 290. Found: C, 82.63; H, 7.57; N, 9.47; mol wt, 283 (calcd).

2,3-Dihydro-5,6-diphenyl-5,5,6,6-tetramethylpyrazine (39). To a solution of benzil in toluene was added 1.65 g of 2,3-diamino-2,3-dimethylbutane.<sup>53</sup> Anhydrous sodium sulfate and a trace of *p*-toluenesulfonic acid were added and the mixture was heated at reflux in a drying tube. After 10-days heating at reflux the solid was removed under reduced pressure and the residue was

chromatographed on a column of 40 g of Florisil. Elution with 50% benzene-Skelly B gave fractions which contained both benzil (1660- $cm^{-1}$  band) and 2,3-diphenyl-5,5,6,6-tetramethylpyrazine (975- $cm^{-1}$  band) by infrared analysis. These fractions were recrystallized from ice-cold acetone solution by the addition of water. This solid was sublimed to give 1.1 g of light yellow needles, mp 92–110° (29% yield). The nmr spectrum consisted of two resonances at  $\delta$  7.40 (relative area 5), *ArH*, and 1.42 (relative area 6),  $CCH_3$ . The infrared spectrum showed strong absorptions at 2880, 1545, 1450, 1160, and 975  $cm^{-1}$ . The ultraviolet spectrum ( $\lambda_{\max}$  223 ( $\epsilon$  12,100), 290 ( $\epsilon$  4150), and 365  $m\mu$  ( $\epsilon$  420)) was also consistent with the assigned structure.

Anal. Calcd for  $C_{26}H_{22}N_2$ : C, 82.72; H, 7.64; N, 9.65; mol wt, 290. Found: C, 82.46; H, 7.61; N, 9.49; mol wt, 285 (benzene).

1,4,5-Trimethylimidazole (6). Crude 4,5-dimethylimidazole<sup>44</sup> (3.0 g) was methylated with 5.0 g of dimethyl sulfate. The product was distilled under reduced pressure to give a colorless oil which became semicrystalline during the distillation, bp 107–109° (18 mm) (lit.<sup>44</sup> 117° (20 mm)). The nmr spectrum consisted of singlets at  $\delta$  7.70 (relative area 1),  $N=CHN$ , 3.62 (relative area 3),  $N-CH_3$ , and 2.38 and 2.29 (relative area 3 each),  $C-CH_3$ . The nmr resonances of the methyl groups in benzene solution appear at  $\delta$  2.80, 2.20, and 1.72, and these compare relatively well with reported values of  $\delta$  2.63, 2.21, and 1.65.<sup>44</sup> The infrared and mass spectrum were consistent with the established structure,<sup>44</sup> with the latter showing a large molecular ion — 1 peak. The picrate, mp 219–220° (lit.<sup>44</sup> mp 218–219°), and methiodide, mp 158–160° (lit.<sup>44</sup> mp 158°), derivatives were prepared.

4,5-Diphenylimidazole was prepared by the method of Davidson, Weiss, and Jelling.<sup>47</sup> The crude product was recrystallized from ethanol-water to give colorless needles, mp 230–231° (lit. 249°,<sup>47</sup> 232–233°<sup>48</sup>).

4,5-Diphenyl-1-methylimidazole (5) was prepared by the method of Simonev and Garnovskii,<sup>49</sup> mp 157.5–158° (lit.<sup>49</sup> 158°). The nmr spectrum consisted of a multiplet at  $\delta$  7.35 (relative area 11), *ArH* and  $N=CHN$ , and a singlet at 3.37 (relative area 3),  $N-CH_3$ . The infrared, ultraviolet, and mass spectra were consistent with the established structure.

1,2-Dimethyl-4,5-diphenylimidazole (18). To 2 g of solid 4,5-diphenyl-2-methylimidazole<sup>47</sup> was added 0.9 ml of dimethyl sulfate (10% excess). The mixture was heated on a steam bath for 24 hr and cooled. A solution of methanol-ammonium hydroxide was added before the solution was poured into sodium hydroxide solution. The aqueous solution was extracted with chloroform, and the chloroform extracts were combined, washed with water, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed under reduced pressure. The residue was recrystallized from ether to give colorless rectangles, mp 121–24°. The nmr spectrum consisted of a multiplet at  $\delta$  7.30 (relative area 10), *ArH*, a singlet at 3.30 (relative area 3),  $N-CH_3$ , and a singlet at 2.44 (relative area 3),  $C-CH_3$ . The infrared spectrum had strong bands at 2950, 1605, and 1400  $cm^{-1}$ .

Anal. Calcd for  $C_{17}H_{14}N_2$ : C, 82.22; H, 6.49; N, 11.28. Found: C, 82.16; H, 6.31; N, 11.08.

2,2-Dimethyl-4,5-diphenylisimidazole (41) was prepared according to the method of Weiss,<sup>50</sup> mp 78–79° (lit.<sup>50</sup> 79–80°). The nmr ( $\delta$  7.46 (relative area 10), *ArH*, singlet at 1.64 (relative area 5.7),  $CCH_3$ ), infrared, and mass spectra were consistent with the established structure.

**General Procedure for Photolysis.** The solutions were photolyzed in a Pyrex container into which the high-pressure mercury vapor lamp and filter in a quartz immersion well or the low-pressure mercury vapor lamp without a filter had been previously placed. The solution was deaerated by a stream of nitrogen before and during photolysis. The nitrogen was purified by passage through two traps of Fieser solution,<sup>51</sup> a lead acetate solution trap, and a drying tower of mixed Molecular Sieve and indicating Drierite. The photolyses were terminated when starting material could not be detected by infrared or ultraviolet spectroscopy.

The crude photolysis mixtures were usually worked up by evaporation of the solvent at reduced pressure, followed by column chromatography on either Florisil (Floridian Co.) or silica gel (E. Merck AG, 0.05–0.20 mm). Unless otherwise noted, the column was eluted with solvents in the following order: 50% benzene–Skelly B, benzene, benzene–1% ether, benzene–2% ether, benzene–5% ether, benzene–10% ether, benzene–25% ether, benzene–50% ether, ether, and more polar solvents as needed. The Skelly B used for chromatography was predistilled; all other solvents used in the chromatographies were reagent grade.

**Light Sources.** The light sources used for photolysis were an Hanovia Type L 450-w high-pressure quartz mercury vapor immersion lamp and an Hanovia 23-w Type SC-2537 low-pressure Vycor mercury vapor immersion lamp. The Pyrex filter sleeve used to restrict the light absorbed by the sample transmits 1, 30, and 70% of the incident light at 280, 300, and 320 m $\mu$ .

**Photolysis of 2,3-Dihydro-5,6-dimethylpyrazine (4).** A solution of 1.27 g of 2,3-dihydro-5,6-dimethylpyrazine (4) in 420 ml of absolute ethanol was photolyzed using a Pyrex-filtered high-pressure lamp. The solvent was removed under reduced pressure and the residue distilled to give 902 mg (71% yield) of clear, colorless oil, bp 107–109° (18 mm), which crystallized on standing. The nmr in deuteriochloroform and benzene, the infrared and ultraviolet spectra, and the melting point of the picrate derivative were identical with those of authentic 1,4,5-trimethylimidazole (6).

**Photolysis of 2,3-Dihydro-5,6-diphenylpyrazine (5).** A solution of 1.00 g of 2,3-dihydro-5,6-diphenylpyrazine (5) in 420 ml of absolute ethanol was photolyzed using a Pyrex-filtered high-pressure mercury vapor lamp. The yellowish solid obtained by evaporation of the solvent was chromatographed on a column of 40 g of Florisil. Elution with benzene–5% ether gave 746 mg (75% yield) of light tan crystals. Recrystallization of this solid from ether gave colorless rectangular crystals, mp 159–160°. This material was identical with authentic 4,5-diphenyl-1-methylimidazole (7) by nmr, infrared, ultraviolet, mass spectral, and mixture melting point criteria.

In a later photolysis of a solution of 1.14 g of 2,3-dihydro-5,6-diphenylpyrazine in 420 ml of absolute ethanol using a Pyrex-filtered high-pressure lamp the crude product was chromatographed on a column of 20 g of silica gel. Elution with 10% ether–benzene gave a crystalline fraction (244 mg) which was rechromatographed on a column of 20 g of silica gel. Elution with 25% ether–benzene gave 100 mg of crystalline material in the first fractions, and this was recrystallized from ether to give colorless rectangles, mp 89.5–91.5°. The compound was identified as 4,5-diphenyl-1-ethoxymethylimidazole (8). The nmr spectrum consisted of a singlet at  $\delta$  7.80 (relative area 1),  $N=CHN$ , a broad multiplet centered at 7.25 (relative area 10),  $ArH$ , a singlet at 5.08 (relative area 2),  $N-CH_2O$ , a quartet at 3.44 (relative area 2,  $J = 7$  cps),  $CH_2CH_3$ , and a triplet at 1.12 (relative area 3,  $J = 7$  cps),  $CH_2CH_3$ . The infrared, ultraviolet, and mass spectra were also consistent with the structure assigned.

*Anal.* Calcd for  $C_{17}H_{18}N_2O$ : C, 77.67; H, 6.52; N, 10.07. Found: C, 77.58; H, 6.40; N, 9.90.

A solution of 76.7 mg of 4,5-diphenyl-1-ethoxymethylimidazole in several milliliters of concentrated HI was refluxed for 7 hr. The acid solution was diluted with distilled water and neutralized with concentrated ammonium hydroxide. The colorless precipitate collected by suction filtration was 44 mg (70% yield) of impure 4,5-diphenylimidazole, mp 205–220°. The crude product was recrystallized from ethanol–water to give colorless needles, mp 228–230°, undepressed upon mixture melting point with authentic 4,5-diphenylimidazole. The infrared and mass spectra of the cleavage product were identical with those of the authentic material.

The photolysis of 5 was carried out in Skelly B, benzene, and 95% ethanol and found to give 7 in yields of 67, 90, and 4%. In the latter case 8 (8%) and 9 (33%) were also obtained. Irradiation of 5 in ethanol for 6 hr using the low-pressure mercury resonance lamp gave 7 in 80% yield.

Approximate quantum yields for the disappearance of 5 and the combined appearance of 7 and 8 were determined to be  $0.13 \pm 0.03$  in ethanol at 25° by ultraviolet analysis with a Pyrex-filtered high-pressure mercury resonance lamp in a thermostated rotating reactor<sup>23</sup> using the photoreduction of benzophenone as an actinometer.<sup>24</sup> The semiquantitative nature of this result should be

noted.<sup>24</sup> The ultraviolet spectra used for the determination of quantum yields did not show an isosbestic point.

Attempts were made to sensitize the photoreaction of 5 in ethanol with benzophenone, triphenylene, and *trans*-stilbene and to quench the reaction with naphthalene or by using perylene as solvent. In all cases the reaction appeared to give the yield of 7 expected in the absence of sensitization or quenching.

**Photolysis of 5 in Ethanol-*d*.** About 250 ml of ethanol-*d* was prepared by the hydrolysis of diethyl sulfite with  $D_2O$ .<sup>25</sup> The ethanol-*d* was distilled, stored over anhydrous sodium carbonate, and redistilled. The pH of the sample was approximately that of absolute ethanol as determined with a Corning pH meter and glass microelectrodes. The deuterium incorporation was determined using the falling drop method.

*Anal.* Calcd for  $C_{17}H_{15}DO$ : 16.6 atom % excess deuterium. Found: 16.6 atom % excess deuterium.

A solution of 852 mg of 2,3-dihydro-5,6-diphenylpyrazine (5) in about 250 ml of ethanol-*d* was photolyzed using a Pyrex-filtered high-pressure lamp for 1.5 hr. After removal of the solvent the semisolid deep yellow residue was chromatographed on a column of 20 g of silica gel. Elution with 5% ether–benzene gave 215 mg of starting material 5. The mass spectrum at low ionizing voltage indicated no incorporation of deuterium. Elution with 25% ether–benzene gave 85 mg of colorless needles identified by nmr and infrared spectra as a slightly impure sample of 4,5-diphenyl-1-ethoxymethylimidazole (8). Elution with 50% ether–benzene gave 135 mg of colorless crystalline solid which was recrystallized from ether to give colorless rectangles, mp 156–159°. The nmr (multiplet at  $\delta$  7.28 (relative area 5),  $ArH$ , unresolved triplet at 3.42 (relative area 1),  $-CH_2D$ ) and infrared spectra were consistent with the expected product, 2-deutero-4,5-diphenyl-1-methyl-*d*-imidazole (36). The sample of the recrystallized imidazole 36 was heated at reflux overnight in ethanol-*d* under a drying tube to ensure complete exchange of the labile imidazole ring proton<sup>26</sup> before mass spectral analysis. At low ionizing voltage the ratio of the molecular ion peaks of this material indicated 8.6%  $C_{17}H_{15}N_2D$  and 91.4%  $C_{17}H_{15}N_2D_2$ . Further elution of the chromatography column with ether gave an additional 103 mg of solid, which was seen by nmr spectroscopy to be composed of about 70% dideuterated imidazole 36. Elution with ethanol gave 204 mg of light yellow solid, mp 212–228°, identified by its nmr, infrared, and mass spectra as 4,5-diphenylimidazole (9). The formation of these products suggests the deuterioethanol contained a small amount of deuterium oxide.

In a control experiment it was shown that 3,4-diphenyl-1-methylimidazole (7) gave only 2-deutero-4,5-diphenyl-1-methylimidazole on photolysis under these conditions.

**Photolysis of *trans*-2,3-Diphenyl-5,6,7,8,9,10-hexahydroquinoxaline (10).** A solution of 1.10 g of *trans*-2,3-diphenyl-5,6,7,8,9,10-hexahydroquinoxaline (10) in 420 ml of absolute ethanol was photolyzed for 7 hr using a Pyrex-filtered high-pressure lamp. The solvent was removed under reduced pressure and the residue was chromatographed on a column of 20 g of silica gel.

Elution with 1% ether–benzene gave 356 mg (32.5% recovery) of light yellow crystals, found to be unreacted 10.

Elution with 2% ether–benzene gave 460 mg (53% yield) of colorless solid which was purified by sublimation at 110° (0.15 mm) to give fine colorless needles, mp 121–123°. The nmr spectrum consisted of a multiplet at  $\delta$  7.28 (relative area 10),  $ArH$ , a multiplet at 5.12 (relative area 1),  $O-CH-N$ , a multiplet at 3.18 (relative area 4),  $CH_2CH_3$ , and  $-CH_2C(=N)$ , a series of multiplets at 1.20–2.50 (relative area 6),  $(-CH_2)_2$ , and a triplet at 1.06 (relative area 3),  $CH_2CH_3$ . The infrared spectrum had strong bands at 2970, 1600, 1443, 1350, 1110, 1090, and 1065  $cm^{-1}$ . The ultraviolet ( $\lambda_{max}$  256 ( $\epsilon$  11,400) and 269 (sh)  $m\mu$  ( $\epsilon$  10,200)) and mass spectra are in qualitative agreement with the structural assignment as 2,3-diphenyl-5-ethoxy-6,7,8,9-tetrahydro-5H-imidazo[1,2-*a*]azepine (12).

*Anal.* Calcd for  $C_{27}H_{24}N_2O$ : C, 79.48; H, 7.28; N, 8.43; mol wt, 332. Found: C, 79.32; H, 7.55; N, 8.56; mol wt, 332 (benzene).

Elution with 10% ether–benzene gave 70 mg (9% yield) of colorless solid. This material was purified by sublimation at 120–130° (0.15 mm) to give colorless crystals, mp 138–140°. The nmr spectrum consisted of a multiplet at  $\delta$  7.30 (relative area 10),  $ArH$ , a multiplet at 3.74 (relative area 2),  $CH_2-N$ , a multiplet at 3.02 (relative area 2),  $-CH_2C(=N)-$ , and a multiplet at 1.82 (relative

$(-\text{CH}_2)_n$ . The infrared spectrum showed strong absorptions at 2910, 1600, and  $1350\text{ cm}^{-1}$ . The ultraviolet and mass spectra were consistent with the assigned structure, 2,3-diphenyl-8,9-dihydro-7H-1,2-azepine (11).

Calcd for  $\text{C}_{20}\text{H}_{18}\text{N}_2$ : C, 83.29; H, 6.99; N, 9.71; mol wt, 282. Found: C, 83.04; H, 6.96; N, 9.56; mol wt, 282.

Elution of 1.06 g of 10 in 420 ml of cyclohexane for 5 hr under the same conditions followed by the same work-up gave 19% of a crystalline material in the benzene-2% ether fractions. This was sublimed to give colorless needles, mp 125–127°. The nuclear magnetic resonance consisted of a multiplet at  $\delta$  7.30 (relative area 10),  $\text{ArH}$ , a doublet (with additional structure) at 6.24 (relative area 1,  $J = 10$  cps),  $\text{NCH}=\text{CH}$ , a singlet at 5.24 (relative area 1),  $-\text{C}=\text{CHCH}_3$ , a multiplet at 3.10 (area 2),  $-\text{CH}_2\text{C}(=\text{O})$ , and multiplets at 1.76–2.60 (relative area 3),  $-\text{CH}_2-\text{CH}_3$ . The infrared spectrum had strong absorptions at 1600, and  $1410\text{ cm}^{-1}$ . The ultraviolet ( $\lambda$  280 m $\mu$ ) and mass spectra were consistent with the structure assigned as 2,3-diphenyl-8,9-dihydro-7H-1,2-azepine (13).

Calcd for  $\text{C}_{20}\text{H}_{18}\text{N}_2$ : C, 83.88; H, 6.34; N, 9.78. Found: C, 83.18; H, 6.18; N, 9.42.

Elution with benzene-10% ether gave 90 mg of 11. Elution with other solvents gave other unidentified products. Catalytic hydrogenation of 76 mg of 13 in ethanol over 10% Pt on charcoal gave, after ca. 1 equiv uptake of hydrogen, 31 mg of 11 by infrared, nmr, and melting point comparison.

**Analysis of *cis*-2,3-Dihydro-2,3-dimethyl-5,6-diphenylpyrazine (14).** A solution of 917 mg of *cis*-2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine (14) in 420 ml of absolute ethanol was photolyzed using a Pyrex-filtered high-pressure lamp for 10 min. The crude product was chromatographed on a column of 20 g of silica gel.

Elution with 1% ether-benzene gave 474 mg of *cis*-2,3-dihydro-2,3-dimethyl-5,6-diphenylpyrazine. No *trans*-dihydro-2,3-dimethyl-5,6-diphenylpyrazine was in the nmr spectrum.

Elution with 5% ether-benzene gave 239 mg (26%) of a crystalline solid purified by vacuum sublimation to give colorless crystals, mp 5°. The nmr spectrum consisted of a multiplet at  $\delta$  7.40 (area 10),  $\text{ArH}$ , a quartet at 5.16, quartet (relative area 1),  $\text{OCH}-\text{CH}_2$ , two overlapping quartets at 3.30 (relative area 2),  $\text{CH}_2\text{CH}_3$ , a singlet at 2.66 (relative area 3), a doublet at 1.60 (relative area 3,  $J = 7$  cps),  $-\text{CHCH}_3$ , a singlet at 1.14 (relative area 3,  $J = 7$  cps),  $\text{CH}_2\text{CH}_3$ . The infrared spectrum had strong absorptions at 2950, 1600, 1385, 1340, and  $1270\text{ cm}^{-1}$ . The ultraviolet and mass spectra were consistent with the structure assigned as 4,5-diphenyl-1-(1-ethoxyethyl)-2-methylimidazole (17).

Calcd for  $\text{C}_{20}\text{H}_{22}\text{N}_2\text{O}$ : C, 78.40; H, 7.24; N, 9.14; mol wt, 305. Found: C, 78.14; H, 7.38; N, 9.14; mol wt, 319.

**Analysis of the partially resolved *cis-trans* mixture of 14.** A solution of 14 (8.7  $\pm$  4.75%) for 9 min in ethanol gave 17 (25%) and 14 (75%). The recovered starting material contained 27% *trans* isomer by nmr and had optical activity of  $[\alpha]_D^{25} -0.68 \pm 0.02^\circ$ ,  $[\alpha]_D^{25} \pm 3.0^\circ$ .

Elution of 190 mg of 17 in 10 ml of concentrated hydriodic acid heated at reflux for 2 days. After cooling the mixture was poured into water and neutralized with concentrated ammonium hydroxide. The precipitate was collected by suction filtration to give 47 mg (97% yield) of 4,5-diphenyl-2-methylimidazole, mp 125–127°, identified by nmr, infrared, and melting point comparison with authentic sample.

**Analysis of 2,3-Dihydro-5,6-diphenyl-2-methylpyrazine (15).** A solution of 1.5 g of 2,3-dihydro-5,6-diphenyl-2-methylpyrazine (15) in 420 ml of absolute ethanol was photolyzed using a Pyrex-high-pressure lamp for 8 hr. The crude product was chromatographed on a column of 20 g of silica gel.

Elution with 1% ether-benzene gave 232 mg (15% recovery) of 15. Elution with 5% ether-benzene gave 272 mg of oil. This oil was solid at 70–90° (0.15 mm) to give a colorless viscous oil. The infrared spectrum showed this to be a mixture of 4,5-diphenyl-1-(1-ethyl)imidazole (20) (singlet at  $\delta$  7.84,  $\text{NCH}=\text{N}$ , multiplets  $\text{ArH}$ , 5.12,  $\text{O}-\text{CHCH}_3$ , and 3.30,  $\text{OCH}_2\text{CH}_3$ , doublet at  $\text{HCH}_3$ , and triplet at 1.08,  $\text{CH}_2\text{CH}_3$ ) and 4,5-diphenyl-1-ethyl-2-methylimidazole (19) (multiplet at  $\delta$  7.30,  $\text{ArH}$ , singlet at 5.00,  $\text{N}-\text{CH}_2-\text{O}$ , multiplet at 3.30,  $\text{O}-\text{CH}_2\text{CH}_3$ , singlet at 1.14, and triplet at 1.08,  $\text{CH}_2\text{CH}_3$ ) in a ratio of 4:3. The ultraviolet and mass spectra were consistent with the assigned mixture.

**Anal.** Calcd for  $\text{C}_{19}\text{H}_{20}\text{N}_2\text{O}$ : C, 78.05; H, 6.90; N, 9.58. Found: C, 77.70; H, 7.11; N, 9.39.

Elution with 10% ether-benzene gave 125 mg of oil. The nmr spectrum of this oil was consistent with a mixture of 4,5-diphenyl-1-ethoxymethyl-2-methylimidazole (19) and 1,2-dimethyl-4,5-diphenylimidazole (18) in a ratio of 2:3. The infrared spectrum was consistent with this mixture.

Elution with 25% ether-benzene gave 627 mg (42% yield) of crystalline material identified as 1,2-dimethyl-4,5-diphenylimidazole (18) by comparison of the nmr and infrared spectra with those of authentic material. Sublimation of the imidazole gave colorless needles, mp 125–127°; a mixture melting point with authentic material was undepressed.

**Photolysis of *d*-2-Isobutyl-2,3-dihydro-5,6-diphenylpyrazine (16).** A solution of 931 mg of *d*-2-isobutyl-2,3-dihydro-5,6-diphenylpyrazine ( $[\alpha]_D^{25} 91.9^\circ \pm 3.3^\circ$ ) in 420 ml of absolute ethanol was photolyzed using a Pyrex-filtered high-pressure lamp for 10 min. The crude product was chromatographed on a column of 20 g of silica gel.

Elution with 1% ether-benzene gave 508 mg of light yellow solid purified by sublimation to give 446 mg (50% recovery) of 16, mp 66.5–69.5°. The nmr and infrared spectra of the sublimed solid were identical with those of starting material. The optical rotation of this material determined using a solution of 228.4 mg of sublimed material in 10 ml of 95% ethanol was  $[\alpha]_D^{25} +2.11 \pm 0.07^\circ$ ,  $[\alpha]_D^{25} +92.2^\circ \pm 3.3^\circ$ .

Elution with 2% ether-benzene gave 30 mg of an oil whose infrared spectrum suggested an ethoxymethylidazole. The nmr spectrum consisted of a multiplet at  $\delta$  7.30,  $\text{ArH}$ , singlet at 5.04,  $\text{NCH}_2-\text{O}$ , quartet at 3.28,  $-\text{CH}_2\text{CH}_3$ , multiplet at 2.70,  $\text{CH}_2-\text{CH}$ , multiplet at 2.30,  $\text{CH}_2\text{CH}(\text{CH}_3)_2$ , doublet and triplet at 1.10,  $\text{CH}(\text{CH}_3)_2$ , and  $\text{CH}_2\text{CH}_3$ , and is consistent with the structure assigned as 2-isobutyl-4,5-diphenyl-1-ethoxymethylimidazole (22).

Elution with 5% ether-benzene gave 194 mg of crystalline solid. The nmr (multiplet at  $\delta$  7.28 (relative area 10),  $\text{ArH}$ , singlet at 3.30 (relative area 3),  $\text{NCH}_3$ , multiplet at 2.68 (relative area 2),  $\text{CH}_2-\text{CH}$ , multiplet at 2.18 (relative area 1),  $-\text{CH}_2\text{CH}(\text{CH}_3)_2$ , and doublet at 1.08 (relative area 6),  $-\text{CH}(\text{CH}_3)_2$ ) spectrum was consistent with 2-isobutyl-4,5-diphenyl-1-methylimidazole (21). The imidazole was purified by sublimation at 100° (0.12 mm) to give fine colorless needles, mp 104–107°. The mass, infrared (KBr disk strong absorptions at 2980, 1600, 770, and  $695\text{ cm}^{-1}$ ), and ultraviolet spectra were consistent with the assigned structure.

**Anal.** Calcd for  $\text{C}_{20}\text{H}_{22}\text{N}_2$ : C, 82.72; H, 7.64; N, 9.65. Found: C, 82.57; H, 7.54; N, 9.49.

Elution with 10% ether-benzene gave 60 mg of partially crystalline material which was composed of 30–40% of 21. The remainder of the material was assigned the structure 4,5-diphenyl-1-(1-ethoxy-4-methylbutyl)imidazole (23) discussed below.

Further elution with 10% ether-benzene gave 93 mg of an oil which was apparently an ethoxymethylidazole. The nmr spectrum (singlet at  $\delta$  7.78 (relative area 1),  $\text{NCHN}$ , multiplet at 7.28 (relative area 10),  $\text{ArH}$ , multiplet at 4.98 (relative area 1),  $\text{O}-\text{CH}(\text{N})-\text{CH}_2$ , quartet at 3.30 (relative area 2),  $\text{O}-\text{CH}_2\text{CH}_3$ , multiplet at 2.68 (relative area 1),  $\text{CH}-\text{CH}(\text{CH}_3)_2$ , multiplet at 1.78 (relative area 2),  $\text{CHCH}_2\text{CH}$ , doublet at 1.08, (relative area 6),  $\text{CH}(\text{CH}_3)_2$ , triplet at 0.80 (relative area 3),  $\text{CH}_2\text{CH}_3$ ) was consistent with an impure sample of 4,5-diphenyl-1-(1-ethoxy-4-methylbutyl)imidazole (23). Attempts to obtain analytical samples of 22 and 23 were not successful.

**Photolysis of *d*-2-Isobutyl-2,3-dihydro-5,6-diphenylpyrazine (16) in Cyclohexane.** A solution of 903 mg of sublimed *d*-2-isobutyl-2,3-dihydro-5,6-diphenylpyrazine (16) in 420 ml of cyclohexane (Fisher Spectral Grade) was photolyzed using a Pyrex-filtered high-pressure lamp for 10 min. The crude product was chromatographed on a column of 22 g of silica gel.

Elution with benzene gave 397 mg (40% recovery) of light yellow crystals sublimed to give 336 mg of 16, mp 68.5–70.5°. The infrared spectrum was identical with that of the starting dihydropyrazine 16. The optical rotation was determined using a 10-ml solution of 228.3 mg of the sublimed solid in 95% ethanol,  $[\alpha]_D^{25} +2.08 \pm 0.08^\circ$ ,  $[\alpha]_D^{25} +91.2^\circ \pm 3.8^\circ$ .

Elution with 1% ether-benzene gave 22 mg of yellow oil which was identified as slightly impure 16 from its infrared spectrum.

Elution with 2% ether-benzene gave 107 mg of off-white solid. The infrared and nmr spectra were identical with those of 2-isobutyl-4,5-diphenyl-1-methylimidazole (21).

Further elution with 5% ether-benzene gave 218 mg of solid, mp 230–270° dec. Although the compound was only slightly soluble in all common organic solvents, it was found that it could be re-

## Thermal Reactions of Azidoformates

David S. Breslow, Thomas J. Prosser, Arnold F. Marcantonio, and C. Arthur Genge

*Contribution from the Research Center, Hercules Inc., Wilmington, Delaware 19899. Received November 4, 1966*

**Abstract:** Kinetic studies have shown that azidoformates decompose thermally in a variety of solvents in a clean first-order reaction, the rate-determining step being evolution of nitrogen and formation of a nitrene. The nitrene reacts with saturated hydrocarbons by insertion into a C–H bond and by abstraction of two hydrogen atoms from adjacent carbons. The insertion reaction is highly selective, the primary:secondary:tertiary reactivity being in the ratio of 1:10:32. The mechanisms of these reactions are discussed.

In a search for new reactions of saturated hydrocarbons, our attention was focused on the reactions of several of Curtius's "starre" or nonrearranging azides: azidoformates, sulfonyl azides, and aryl azides.<sup>1</sup> It was felt that, if these compounds decompose by loss of nitrogen and formation of an electron-deficient nitrene

(1) A. Bertho, *J. Prakt. Chem.*, [2] **120**, 89 (1929).

species, the nitrene might insert into a carbon–hydrogen bond, in analogy to the well-known carbene reaction. If the reaction followed this course, monofunctional compounds could be used to introduce polar groups into saturated hydrocarbon polymers, such as polyethylene and polypropylene, while difunctional derivatives could be used as cross-linking agents for these polymers as

s for saturated hydrocarbon elastomers, such as neopropylene copolymers and polyisobutylene. High peroxides can be used to cross-link polyene and ethylene-propylene copolymers, free radicals are known to degrade polypropylene and isobutylene when used in small quantities.<sup>2</sup>

This paper describes our experience with azidoformates.<sup>3</sup> When this work was initiated, the literature devoid of any pertinent references. Methyl,<sup>4,5</sup> ethyl,<sup>6</sup> and *t*-butyl<sup>7</sup> azidoformates had been described, except for the work of Curtius and Klavehn<sup>8</sup> on 1,3-diphenyl cycloaddition of the azide group to acetylenic compounds, the references described essentially only the nucleophilic displacement of the azide group from the azidoformate.<sup>9</sup>

3

Our preliminary experiments showed that the thermal decomposition of an alkyl azidoformate in diphenyl ether did indeed give an N-cyclohexylcarbamate as one of the products of the reaction, a study of the kinetics of azidoformate decomposition in a variety of solvents was initiated. The kinetic runs were carried out by determining the increase in pressure at constant volume by means of a transducer connected to a recorder; a read-out device enabled one to take individual measurements. *n*-Octadecyl azidoformate was chosen because it could be purified by recrystallization, it is nonvolatile and its low volatility simplified the kinetics; tetramethylene bis(azidoformate) was chosen as a diatomic compound.<sup>11</sup>

A representative run with *n*-octadecyl azidoformate in diphenyl ether is illustrated in Figure 1. The reaction is clearly first order to 95% reaction; at 120°, *n*-octadecyl azidoformate has a half-life of 48.1 min. Figure 1 shows that the rate constant is independent of concentration at two different temperatures and that the reaction is essentially quantitative. Tetramethylene bis(azidoformate), in which the two azidoformate groups are separated by only four carbon atoms, gives essentially the same rate. The aromatic bis(azidoformate), 2,2-bis(4-azidocarbonyloxyphenyl)propane, is much less stable; at 120° it has a half-life of 33.4 min. The decomposition of both the *n*-octadecyl and the tetramethylene azidoformates  $\Delta H^\ddagger$  is 29.9 kcal/mole  $S^\ddagger$  is +4.7 eu.

The first-order decomposition of azidoformates is catalyzed by a wide variety of reagents. Potassium hydroxide, *p*-toluenesulfonic acid, fatty acid salts of sodium, calcium, zinc, cadmium, copper, lead, manganese, cobalt, and nickel, titanium(IV) naphthenate,

Table II lists the first-order rate constants for the decomposition of *n*-octadecyl azidoformate in a variety of solvents. Good first-order plots were obtained to better than 75% reaction in most of these solvents; deviations from first order were observed in the fatty acid after 50% and in 2-heptanone after 65%. Since the excess gas in the fatty acid run was identified as carbon dioxide, apparently a concurrent reaction disturbed the normal first-order kinetics; the reason for the low gas yield and the poor kinetics in 2-heptanone has not been explained. The less than fourfold variations in rate can undoubtedly be attributed to the widely varied nature of the solvents rather than to different mechanisms.<sup>13</sup>

(13) Huisgen and Blaschke<sup>14</sup> have recently reported similar results for the thermal decomposition of *n*-propyl azidoformate in anethole,

<sup>a</sup> 0.10 *M* in *n*-octadecyl azidoformate.

To determine the products of the reaction, an attempt was made to obtain a complete material balance in the reaction of *n*-octadecyl azidoformate with cyclohexane. Separations were made using a "Scanalyzer," a liquid-solid chromatographic apparatus in which the polarity of the eluting solvent is increased automatically; the previously described apparatus<sup>15</sup> was modified to monitor fractions by infrared rather than by ultraviolet, as described in the Experimental Section. The results obtained by heating a 1.25% solution of the azidoformate in cyclohexane at 130° are given in Table III; it

**Table III.** Reaction of *n*-Octadecyl Azidoformate with Cyclohexane at 130°

Fraction	Product	— Mole % of — initial azide	
		<i>m</i> -C <sub>6</sub> H <sub>4</sub> (NO <sub>2</sub> ) <sub>2</sub> absent	<i>m</i> -C <sub>6</sub> H <sub>4</sub> (NO <sub>2</sub> ) <sub>2</sub> present

		95.1	100.4

was gratifying to be able to account for 95% of the initial azide. Fraction I was identified as *n*-octadecyl carbonate, an impurity present in this sample of azidoformate. The major product of the reaction, *n*-octadecyl *N*-cyclohexylcarbamate (fraction II), is formed by insertion of the nitrene moiety into a C-H bond of cyclohexane. However, there is also a considerable amount of the hydrogen abstraction product, *n*-octadecyl carbamate (fraction III).<sup>16</sup> Fractions I-III were identified

ethyl 10-undecenoate, benzonitrile, phenylacetylene, diphenylacetylene, diphenyl ether, mesitylene, and paraffin. Although their rates seemed to be about one-third slower than ours and their result in paraffin was abnormal, their rate constants varied by only a factor of 4 in the different solvents.

(14) R. Huisgen and H. Blaschke, *Chem. Ber.*, **98**, 2985 (1965).(15) W. C. Kenyon, J. E. McCarley, E. G. Boucher, A. E. Robinson, and A. K. Wiebe, *Anal. Chem.*, **27**, 1888 (1955).(16) Lwowski and Mattingly<sup>17</sup> have recently reported a 51% yield of *N*-cyclohexylurethan and a 12% yield of urethan from the photolysis of ethyl azidoformate in cyclohexane. Huisgen and Blaschke<sup>14</sup> reported a

by comparison with authentic specimens. Fractions IV and V, which accounted for 12.7% of the initial azide, are isomeric materials which analysis showed to be C<sub>18</sub>H<sub>37</sub>O<sub>2</sub>N; they are therefore intramolecular condensation products of the nitrene. Fraction IV was shown to be 4-*n*-hexadecyl-2-oxazolidinone by comparison of its infrared and nmr spectra with those of an authentic sample of the 4-ethyl derivative. Thus, both compounds showed carbonyl absorption at 1760 cm<sup>-1</sup>. In very similar nmr spectra, both compounds showed four hydrogens in addition to those in the alkyl side chain, a multiplet (2 H) centered at about  $\tau$  6.4 for the two hydrogens adjacent to oxygen, a multiplet (1 H) centered at about  $\tau$  5.9 for the one hydrogen adjacent to nitrogen, and a broad line (1 H) for the amide hydrogen at about  $\tau$  2.4.

Although fraction V would be expected to be the corresponding six-membered ring compound, 4-*n*-pentadecyltetrahydro-2H-1,3-oxazin-2-one, comparison with the analogous 4-methyl derivative probably excludes this structure. Thus, the 4-methyl derivative showed carbonyl absorption at 1704 cm<sup>-1</sup>, while fraction V in various samples absorbed in the 1725-cm<sup>-1</sup> region. The presence of an absorption band at 3250 cm<sup>-1</sup> typical of N-H in a secondary amide together with the complete absence of an amide II band indicates a cyclic amide structure. In the nmr spectrum, the 4-methyl derivative showed the expected pattern: a multiplet (2 H) centered at  $\tau$  8.14 for the middle methylene hydrogens, a multiplet (2 H) centered at  $\tau$  6.64 for the two hydrogens adjacent to oxygen, a multiplet (1 H) centered at  $\tau$  5.58 for the one hydrogen adjacent to nitrogen, and a broad line (1 H) for the amide hydrogen at  $\tau$  2.76. Fraction V showed only three types of hydrogen in addition to those in the side chain: a broad line (1 H) at  $\tau$  6.86, a broad line (2 H) at  $\tau$  5.90, and a broad line (1 H) at  $\tau$  2.06. The absence of the expected middle methylene peak is not significant, since, if present, it would have been buried under the large side-chain peak. The difficulty arises from the peak for the two hydrogens being downfield from that for the one hydrogen, the direct inverse of the pattern for the 4-methyl derivative. Unfortunately, lack of material precluded further investigation.

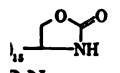

On the basis of the assumption that hydrogen abstraction might be a radical reaction, the decomposition of *n*-octadecyl azidoformate in cyclohexane was carried out in the presence of a small amount (0.25% based on cyclohexane) of a potential radical trap, *m*-dinitrobenzene. The results, shown in Table III, were quite surprising. Although the yield of hydrogen-abstraction product was indeed decreased, the yield of insertion product was increased. There was no reaction with the *m*-dinitrobenzene; all the azidoformate added could be accounted for by reaction with cyclohexane or with itself.

That the results with *m*-dinitrobenzene are well outside of experimental error was demonstrated by carrying out the decomposition in methylcyclohexane, without added nitro compound. Although the various insertion isomers were not separated from each other, the yields of the different types of products were prac-

78% yield of *N*-cyclohexylurethan in the same experiment, but details are lacking.(17) W. Lwowski and T. W. Mattingly, Jr., *J. Am. Chem. Soc.*, **87**, 1947 (1965).

able results were obtained in the decomposi-  
ramethylene bis(azidoformate) in cyclohexane.  
2% yield of tetramethylene bis(N-cyclohexyl-  
), from C-H insertion at both ends, 36% of  
ylene N-cyclohexyldicarbamate, from inser-  
e end and hydrogen abstraction at the other,  
; of tetramethylene dicarbamate, from ab-  
at both ends, were isolated. Based on the  
f azidoformate groups, 50% of the reaction  
C-H insertion and 27% hydrogen abstraction,  
able agreement with the *n*-octadecyl azido-  
results, considering that only 77% of the ma-  
accounted for.

ermine the source of the hydrogen in the  
ited carbamate, the decomposition of an 11%  
of *n*-octadecyl azidoformate in cyclohexane  
tigated. Cyclohexene was identified in the  
action by mass spectrographic analysis; as-  
e same amount of unsubstituted carbamate  
ed as in the more dilute reaction, the cyclo-  
eld, based on the amount of *n*-octadecyl  
formed, was 42%. The low yield is not  
in view of the finding by Lwowski and  
17 that the double bond in cyclohexene reacts  
mally generated ethoxycarbonylnitrene 36  
er than do the nonallylic methylene groups;  
ork no attempt was made to isolate the ex-  
iridine. No trace of bicyclohexyl could be  
either gas chromatographic or mass spectro-  
analysis.

ermine the relative reactivities of different  
ds toward insertion, ethyl azidoformate was  
ed in 2-methylbutane, the products being  
by gas chromatography. After correction  
umber of hydrogens, the relative reactivities

y:secondary:tertiary C-H bonds were found  
1:32.

## Discussion

There would appear to be little doubt from the kinetic results that the rate-determining step in the thermal decomposition of azidoformates is the loss of nitrogen and the formation of an electron-deficient nitrene species, in complete agreement with the elegant work of Lwowski and his co-workers on the photochemical decomposition. The reaction of *n*-octadecyl azido-

formate with cyclohexane can then be pictured as follows:

About 65% of the azidoformate undergoes insertion, either intra- or intermolecularly, and about 20% undergoes hydrogen abstraction by a process of removing two hydrogen atoms from adjacent carbons.

Several examples of 2-oxazolidinone formation have been reported recently. Thus, Smolinsky and Feuer<sup>18</sup> obtained a 68% yield of the 4-methyl-4-ethyl derivative by vapor-phase decomposition of 2-methylbutyl azidoformate, conditions under which intermolecular reactions would be minimized. The fact that *t*-butyl azidoformate, upon irradiation in the reactive solvent, *t*-butyl alcohol, cyclizes to the 4,4-dimethyl derivative in 60–75% yield<sup>19,20</sup> is probably a reflection of the well-known *gem*-dimethyl effect, while the complete absence of 2-oxazolidinone in the decomposition of ethyl azidoformate under a variety of conditions<sup>17</sup> is probably a result of the lower activity of a primary as compared to a secondary C-H bond. Although it appears rather unlikely that the unknown isomer in the reaction is the six-membered cyclic carbamate, intramolecular nitrene insertion to give a six-membered ring is not without precedent; several examples of  $\delta$ -lactam formation by photolysis of carbonyl azides have been reported.<sup>21,22</sup>

The reactivity of a formylnitrene toward insertion into a C-H bond is remarkably independent of its modes of formation. As shown in Table V, essentially identical results are obtained by azide thermolysis, by azide photolysis, and by  $\alpha$  elimination. In view of the quite high selectivity found, there must be considerable resonance stabilization of the nitrene, *e.g.*

<sup>a</sup> W. Lwowski and T. J. Maricich, *J. Am. Chem. Soc.*, **87**, 3630 (1965).

Some progress is being made in determining the nature of the nitrene, singlet or triplet, responsible for its different reactions. Considering the relatively low temperature at which nitrene can be formed from azide, it is highly likely that nitrene is formed initially as a singlet.<sup>23</sup> This can then react with substrate to give products, or it can decay to ground-state triplet<sup>25</sup>

which in turn can react with substrate. The facts that tetramethylene bis(azidoformate) cross-links polyisobutylene,<sup>30</sup> whereas radicals are known to lead to degradation,<sup>3</sup> and that the insertion reaction can be highly stereospecific,<sup>18,31</sup> argues for singlet nitrene being involved in C-H insertion. However, recent work with cyanogen azide<sup>32</sup> indicates that a triplet nitrene can insert nonstereospecifically. Thus, the spin multiplicities involved in C-H insertion seem to parallel quite closely those involved in addition to a carbon-carbon double bond. Here, too, Lwowski and McConaghy<sup>33</sup> concluded that both singlet and triplet nitrene add, the former stereospecifically and the latter nonstereospecifically.

There is much less evidence available at present regarding hydrogen abstraction. It seems to be fairly certain from our results that two hydrogen atoms are abstracted from adjacent carbon atoms in a concerted fashion,<sup>34</sup> or at least in rapid consecutive reactions, since the formation of free cyclohexyl radicals would have been expected to lead to the formation of at least some bicyclohexyl. Although there is no *a priori*

(23) If the law of spin conservation is to be obeyed, a nitrene triplet can be the initial product if singlet azide decomposes into triplet nitrene and triplet nitrogen, or if singlet azide is first converted into triplet azide, which then decomposes into triplet nitrene and singlet nitrogen. Neither path seems very likely at decomposition temperatures in the vicinity of 100°.<sup>34</sup>

(34) A referee has suggested that a concerted reaction is unlikely because the two C-H bonds are skew. In view of the rapid interconversion of cyclohexane structures, we do not consider this a valid objection.

reason for eliminating the possibility of this being a singlet reaction, it is easier to explain our results with *m*-dinitrobenzene on the basis of hydrogen abstraction involving a triplet nitrene. Although the mechanism of action of nitroaromatics as inhibitors of free-radical reactions may be uncertain, they appear to inhibit by reacting with free radicals.<sup>35</sup> Although the yield of hydrogen abstraction product was indeed reduced by the addition of *m*-dinitrobenzene, all of the azidoformate was accounted for as reaction products with cyclohexane or with itself. If the same nitrene species (singlet or triplet) were responsible for both insertion and abstraction, one would have expected *m*-dinitrobenzene to decrease the insertion yield as well, whereas in actual fact the yield of insertion product in the presence of *m*-dinitrobenzene actually increased over that obtained in its absence. If one assumes that C-H insertion under these conditions involves a singlet nitrene, then hydrogen abstraction probably involves a triplet.

## Experimental Section

**Preparation of Chloroformates.** Several different procedures were used to prepare the chloroformates. *n*-Octadecyl chloroformate was prepared as follows. To 198 g (2 moles) of phosgene in a flask connected to a Dry Ice condenser was added 270.5 g (1 mole) of molten 1-octadecanol over a period of 90 min, the reaction being kept at 5–10° by external cooling. The cooling bath was then removed and the reaction stirred for 5 hr. The Dry Ice condenser was removed and the excess phosgene was allowed to evaporate overnight, the last traces being removed *in vacuo*. A quantitative yield of chloroformate was obtained as a clear yellow oil; the absence of a hydroxyl band in the infrared spectrum indicated the completeness of the reaction.

To 70 ml of carbon tetrachloride in a flask attached to a Dry Ice condenser was added 45 g (0.5 mole) of tetramethylene glycol while 114 g (1.15 moles) of phosgene was passed in. The reaction was kept at 10–15° during the addition, which took 45 min. The reaction mixture was stirred at 15° for an additional 4.5 hr, the Dry Ice condenser was removed, and the solution was refluxed to remove excess phosgene. Stripping the solvent *in vacuo* left 106 g of tetramethylene bis(chloroformate), an essentially quantitative yield. Although pure enough for subsequent reaction, the material could be further purified by distillation, bp 126° (5–6 mm).

A solution of 46 g (0.2 mole) of 2,2-bis(4-hydroxyphenyl)propane in 300 ml of ether was added to 49 g (0.5 mole) of phosgene cooled below 0° in an ice-salt bath. To the stirred and cooled resulting white slurry was then added dropwise 60.5 g (0.5 mole) of dimethylaniline. The mixture was stirred in the cooling bath for an additional hour and allowed to warm to room temperature overnight, and the solvent and excess phosgene were removed *in vacuo*. The residual solid was suspended in 400 ml of ether and poured onto ice, and the organic layer was separated. After being washed once with 5% hydrochloric acid and then with water, the solution was dried over sodium sulfate and the solvent evaporated. There was thus obtained 60 g (85%) of 2,2-bis(4-chlorocarbonyloxyphenyl)propane, mp 93–96°. Recrystallization from heptane gave a 77% yield of product melting at 96.5–98.5°.

**Preparation of Azidoformates.** A solution of 16.7 g (0.05 mole) of *n*-octadecyl chloroformate in 100 ml of chloroform was added dropwise to a vigorously stirred solution of 6.5 g (0.10 mole) of sodium azide in 15 ml of water at room temperature. The reaction mixture was stirred vigorously at room temperature for 3 days, and the organic layer was separated, washed several times with water, and dried over a mixture of magnesium and sodium sulfates. Removal of the solvent yielded 16.5 g (97%) of crystalline *n*-octadecyl azidoformate, mp 37.8–38.8°.

*Anal.* Calcd for C<sub>19</sub>H<sub>37</sub>N<sub>3</sub>O<sub>2</sub>: C, 67.21; H, 10.99; N, 12.38; O, 9.43. Found: C, 67.54; H, 11.07; N, 12.16; O, 9.07. For the kinetic runs, a sample was recrystallized several times from methanol, mp 41.0–41.5°.

(35) C. Walling, "Free Radicals in Solution," John Wiley and Sons, Inc., New York, N. Y., 1957, p 169.

same procedure, tetramethylene bis(chloroformate) was into tetramethylene bis(azidoformate) in 96% yield, after recrystallization from ethanol-hexane.

Calcd for  $C_4H_8N_4O_4$ : C, 31.58; H, 3.53; N, 36.84; Found: C, 31.57; H, 3.27; N, 37.05; O, 28.19.

4-azidocarbonyloxyphenylpropane was obtained in 92% 69–70.5° after recrystallization from ethanol.

Calcd for  $C_{17}H_{14}O_4N_4$ : C, 55.74; H, 3.86; N, 22.93; Found: C, 56.29; H, 3.72; N, 23.16.

**Runs.** The reactor consisted of a 200-ml creased flask neck ending in a 29/42 standard-taper female joint. The joint was a side arm closed off by a pressure stopcock; this was a glass-enclosed magnet on which the sample cup. The entire apparatus was immersed in an oil bath  $\pm 0.01^\circ$ ; the reaction was stirred by a magnetic stirring driving magnet drive being placed just below the oil bath. The transducer built into a stainless-steel 29/42 standard joint was used to determine pressure changes. The connected through the side arm to a thermostated gas also to a 100-cm, closed-end manometer to determine pressure; the entire system could be evacuated or filled with inert gas.

Initially, the desired volume of solvent was placed in the side arm and the azidoformate, in a small glass sample cup, was set in the magnet. After the transducer was inserted and clamped, the apparatus was alternately evacuated to about 2 mm and filled with an inert gas, nitrogen or argon, to a pressure of about 1 atm.

Finally, the apparatus was filled with inert gas to a pressure in excess of 1 atm, and the reactor was lowered into the thermostated bath. During equilibration, the reactor was allowed to maintain the pressure at about 780 mm. Pressure had become constant (usually 0.5–1 hr), the bar was retracted, and the sample cup was dropped into the hot bath. Pressure was recorded automatically on a strip chart recorder at 2 in./hr. For rapid reactions, the pressure was read from a digital read-out system. At the end of the run, the sample removed in the reaction was bled to the thermostated gas bath after equilibration, the pressure in the system was adjusted to the initial pressure by manipulating the mercury level in the gas manometer. The theoretical reaction gas volume was calculated in the usual way from the known sample weight, and temperature data.

**Chromatographic Separations.** The products from reaction of azidoformate with cyclohexane or methylcyclohexane were separated on adsorbent columns 17 cm long and 1.8 cm i.d., containing 100 parts by weight of Woelm neutral alumina and 6 parts by weight of 60/80 mesh Porapak Q.

The two-bottle gradient solvent system comprised about 100 ml of a relatively nonpolar solvent in a 9.6-cm i.d. bottle and 100 ml of a more polar solvent in a 5.2-cm i.d. bottle.

Chromatographic separations were made in an automated system which used an infrared spectrophotometer (Perkin-Elmer Model 237-B) as the detector. This was set to scan over the carbonyl region, 1850–1650  $\text{cm}^{-1}$ . This apparatus is similar to the "analyzer" previously described<sup>18</sup> which used an ultraviolet spectrophotometer as the detector. A typical run produced 10 cuts which were stored in a fraction collector. A strip chart recorded the carbonyl absorbance of each chromatographic fraction. The carbonyl absorbance of the several components of a sample was isolated by selectively combining the pertinent cuts and evaporating solvent. Weight per cent analysis was obtained; typical recoveries of 95–98 wt %.

Different solvent systems were used in these chromatographic separations. One system used 0.4 vol % ethanol in chloroform in the 9.6-cm bottle and 1.6 vol % ethanol in chloroform in the 5.2-cm bottle. A chloroform-free chloroform was obtained by passing Mallinckrodt analytical reagent chloroform through an alumina column. This gave good separation of fractions I–III but did not separate fractions IV and V (Table III); the presence of these two in a combined elution band was readily apparent because of the difference in carbonyl frequencies, 1760 vs. 1730  $\text{cm}^{-1}$ .

In earlier work, this mixture of fractions IV and V was separated by chromatography, again on the alumina and 6% water using *n*-heptane as the nonpolar solvent and 10 vol % ethanol in *n*-heptane as the polar solvent. In later work, complete resolution of all five components in the mono- and dihydrocarbon reaction mixture was achieved using a mixture consisting of 1 vol % of acetonitrile in carbon tetrachloride in the larger bottle and 20 vol % of acetonitrile in carbon tetrachloride in the smaller bottle.

**Reaction of *n*-Octadecyl Azidoformate with Cyclohexane.** *n*-Octadecyl carbamate was prepared by passing ammonia into a cold solution of 1 g of *n*-octadecyl chloroformate in 250 ml of ether. Filtration to remove ammonium chloride, evaporation of the solvent, and recrystallization of the residue from aqueous acetone yielded 1.2 g (82% of theory) of product, mp 101.5–103°.

Anal. Calcd for  $C_{19}H_{37}O_2N$ : C, 72.78; H, 12.54; N, 4.47. Found: C, 72.68; H, 12.54; N, 4.56.

*n*-Octadecyl *N*-cyclohexylcarbamate was prepared by refluxing a solution of 2.71 g (10 mmoles) of 1-octadecanol, 1.38 g (11 mmoles) of cyclohexyl isocyanate,<sup>36</sup> and 0.27 g of triethylamine in 25 ml of chloroform. Removal of solvent and recrystallization from acetone yielded 3.26 g (83% of theory) of white solid, mp 68.5–69.5°.

Anal. Calcd for  $C_{24}H_{44}O_2N$ : C, 75.88; H, 12.48; N, 3.54. Found: C, 75.98; H, 12.87; N, 2.94.

4-Ethyl-2-oxazolidinone was prepared in 47% yield from 2-amino-1-butanol and ethyl carbonate according to the procedure of Homeyer,<sup>37</sup> bp 129–131° (0.5 mm),  $n_D^{20}$  1.4637, mp 17° (lit.<sup>37</sup>  $n_D^{20}$  1.4631, mp 16.0–16.5°).

Anal. Calcd for  $C_6H_{10}O_2N$ : N, 12.17. Found N, 12.20.

4-Methyltetrahydro-2H-1,3-oxazin-2-one was prepared in the same fashion from 3-amino-1-butanol. Recrystallization from acetone gave a 39% yield of product, mp 98.5–99.5° (lit.<sup>38</sup> mp 91°).

Anal. Calcd for  $C_8H_{12}O_2N$ : C, 52.16; H, 7.88; N, 12.17. Found: C, 52.13; H, 7.89; N, 12.14.

Solutions of 1.00 g (2.95 mmoles) of *n*-octadecyl azidoformate in 100 ml of cyclohexane (Eastman Kodak Spectro Grade) were heated at 130° under nitrogen in capped pressure bottles for 16 hr. Eight such runs were combined, using chloroform to rinse the bottles. Removal of the solvent *in vacuo* left 8.745 g of solid.

The acetonitrile-carbon tetrachloride solvent system gave five fractions (Table III). Fraction I (1.9 wt %) had an infrared spectrum very similar to that of decyl carbamate; it is presumably octadecyl carbamate, present as a minor impurity in the azidoformate, and the yield calculations were corrected accordingly. Fraction II (62.6 wt %) analyzed correctly for *n*-octadecyl *N*-cyclohexylcarbamate, and its melting point and infrared spectrum agreed with those of an authentic sample. In the same way fraction III (18.7 wt %) was identified as *n*-octadecyl carbamate. Fraction IV (4.1 wt %) was identified as 4-*n*-hexadecyl-2-oxazolidinone, mp 60.5–62° after recrystallization from aqueous acetone.

Anal. Calcd for  $C_{19}H_{37}O_2N$ : C, 73.25; H, 11.97; N, 4.50; mol wt, 311. Found: C, 72.94; H, 12.10; N, 4.36; mol wt (Rast), 295.

The infrared and nmr spectra of fraction IV were very similar to those of 4-ethyl-2-oxazolidinone. Fraction V (6.7 wt %), mp 75.5–77° after recrystallization from aqueous acetone, was an isomer of fraction IV.

Anal. Calcd for  $C_{19}H_{37}O_2N$ : C, 73.25; H, 11.97; N, 4.50; mol wt, 311. Found: C, 73.45; H, 12.25; N, 4.43; mol wt (Rast), 309.

To determine the source of the hydrogen in the unsubstituted carbamate, 1.00 g of *n*-octadecyl azidoformate was decomposed in 10 ml of cyclohexane as described above. Mass spectral analysis showed the presence of  $0.30 \pm 0.05$  mole % of cyclohexene.<sup>39</sup> This corresponds to a 42% yield of cyclohexene, if a 22% yield of unsubstituted carbamate is assumed.

**Reaction of *n*-Octadecyl Azidoformate with Cyclohexane in the Presence of *m*-Dinitrobenzene.** A solution of 2.00 g of *n*-octadecyl azidoformate and 0.50 g of *m*-dinitrobenzene in 200 ml of cyclohexane was heated for 17 hr at 130° as described above. Removal of solvent left 2.750 g of residue.

Chromatographic separation of the product gave fractions II–V; *n*-octadecyl carbamate, previously separated as fraction I, was apparently absent from this sample of azidoformate. Fraction II, *n*-octadecyl *N*-cyclohexylcarbamate, did contain a yellow contaminant which did not show carbonyl absorbance. Rechromatography on a similar column, using carbon tetrachloride and 5 vol % of diethyl ether in carbon tetrachloride in the 9.6- and 5.2-cm

(36) A. Skita and H. Rolfes, *Ber.*, 53B, 1248 (1920).

(37) A. H. Homeyer, U. S. Patent 2,399,118 (1946).

(38) A. M. Paquin, *Z. Naturforsch.*, 1, 518 (1946).

(39) We are indebted to P. W. Shearer of this laboratory for this determination. Since cyclohexane has a small peak contribution at  $M - 2$  ( $m/e$  82, the parent ion for cyclohexene), a fresh calibration sample of cyclohexane (Eastman Kodak Spectral Grade) was run immediately preceding the questioned samples. This calibration pattern was then used to apply the proper correction on the  $M - 2$  ( $m/e$  82) peak, leaving the residual  $m/e$  82 free for calculating cyclohexene. Relative sensitivities for constituents reported were based on our instrumental parameters.

bottles, respectively, separated the yellow contaminant from fraction II. Infrared indicated that most of this contaminant was *m*-dinitrobenzene, but unidentified material was present also. Fractions II–V were identical by infrared with the analogous components discussed above and accounted for 100.4 mole % of the initial azidoformate. Thus, the contaminants, 14.2 wt % of the sample, apparently were not derived from the azidoformate.

**Reaction of *n*-Octadecyl Azidoformate with Methylcyclohexane.** Solutions of 1.00 g of azidoformate in 100 ml of methylcyclohexane were treated as described above. From eight runs, 8.20 g of yellow-white solid was obtained.

Chromatographic separative analysis of the reaction product also produced five fractions (Table IV). Fraction I was *n*-octadecyl carbonate (2.5 wt %). Fraction II was a mixture of isomeric *n*-octadecyl *N*-methylcyclohexylcarbamates (66.1 wt %).

*Anal.* Calcd for  $C_{28}H_{54}O_2N$ : C, 76.22; H, 12.55; N, 3.42; mol wt, 410. Found: C, 75.74; H, 12.30; N, 3.28; mol wt (Rast), 400.

Rechromatographing fraction II on neutral alumina and 6% water with 2.0 vol % of diethyl ether in petroleum ether (bp 45–70°) in the 9.6-cm solvent bottle and 8.0 vol % of diethyl ether in petroleum ether in the 5.2-cm bottle showed the presence of at least three components. One component (25%) was resolved from the mixed elution band containing the other two. The latter were approximately in the ratio of 2:3 in order of elution. Infrared spectra of these three components showed differences, but these were not readily interpreted in terms of structure. Fractions III (20.4 wt %), IV (3.8 wt %), and V (6.6 wt %) were identical with those described above.

**Reaction of Tetramethylene Bis(azidoformate) with Cyclohexane.** Tetramethylene bis(carbamate) was prepared from the chloroformate and ammonia in 92% yield according to Rabjohn,<sup>40</sup> mp 197–198°.

Tetramethylene bis(*N*-cyclohexylcarbamate) was prepared from 1.00 g (11 mmoles) of 1,4-butanediol, 3.20 g (26 mmoles) of cyclohexyl isocyanate,<sup>41</sup> and 2 drops of triethylamine. The resulting white solid was filtered and recrystallized several times from aqueous acetone, yielding 2.66 g of product (71% of theory), mp 178.5–180.5°.

*Anal.* Calcd for  $C_{18}H_{32}O_4N_2$ : C, 63.49; H, 9.47; N, 8.23. Found: C, 63.48; H, 9.62; N, 8.94.

Solutions of 1.00 g of azidoformate in 100 ml of cyclohexane were treated as described above. From eight runs there was obtained 9.95 g of yellow-white solid. This material was incompletely soluble in chloroform; 1.00 g gave 53 mg of crystalline solid whose analysis, melting point, and infrared spectrum identified it as tetramethylene bis(carbamate).

Oils and other extraneous matter in the soluble portion of the sample were removed by passage through a chromatographic column of activated charcoal (Darco G60) 10 cm high and 1.8 cm in diameter; 87% of the sample was recovered by chloroform elution. This material was chromatographed on the alumina and 6% water

column in the "Scanalyzer" with the ethanol-chloroform solvent system. The first fraction eluted accounted for 38.9 wt % of the original sample. Comparison of analysis, melting point, and infrared spectrum with those of a synthetic sample showed this fraction, recrystallized from acetone-*n*-heptane, was tetramethylene bis(*N*-cyclohexylcarbamate). It accounted for 32.3 mole % of the initial azidoformate.

The second fraction eluted in the "Scanalyzer" run, 35.9 wt %, was indicated by its infrared spectrum to be tetramethylene *N*-cyclohexylcarbamate.

*Anal.* Calcd for  $C_{12}H_{22}O_4N_2$ : C, 55.79; H, 8.58; N, 10.85. Found: C, 55.98; H, 8.73; N, 10.79.

The infrared spectrum indicated the presence of both –CONH<sub>2</sub> and –CONHC<sub>6</sub>H<sub>11</sub>. The same four N–H bands shown by tetramethylene bis(carbamate) at 3410, 3300, 3245, and 3200 cm<sup>–1</sup> were present, indicating NH<sub>2</sub>. Except for the 3300-cm<sup>–1</sup> band, these bands were in the correct ratios of intensities. The more intense 3300 cm<sup>–1</sup>, which was exhibited also by the tetramethylene bis(*N*-cyclohexylcarbamate), indicated the presence of –NHC<sub>6</sub>H<sub>11</sub> in this second fraction. Corroborating evidence for the –CONH<sub>2</sub> grouping was the amide II band at 1615 cm<sup>–1</sup>. The presence of a –CONHC<sub>6</sub>H<sub>11</sub> grouping was indicated by the amide II band at 1530 cm<sup>–1</sup>.

An additional elution band containing at least two components (two carbonyl bands at 1760 and 1700 cm<sup>–1</sup>) was isolated. Limited work on rechromatographing this mixed fraction was unsuccessful in attaining adequate separation.

**Reaction of Ethyl Azidoformate with 2-Methylbutane.** Isoamylamine, 2-methylbutylamine, and *t*-amylamine were commercial materials (K & K Laboratories). 2-Amino-3-methylbutane was prepared by the reductive amination of 3-methyl-2-butanone according to the procedure of Schwoegler and Adkins,<sup>41</sup> bp 86.5–86.8°, *n*<sub>D</sub><sup>20</sup> 1.4032. The amines were then converted to the corresponding urethans by reaction with ethyl chloroformate according to the procedure of Hartman and Brethen.<sup>42</sup> Gas chromatography indicated the compounds to be 94–98% pure without distillation. One sample was purified by preparative-scale gas chromatography and was shown to have an infrared spectrum identical with that of the crude material, indicating that no decomposition had taken place on the chromatographic column.

To determine reactivities, a solution of approximately 1.5 g of ethyl azidoformate in 40 ml of 2-methylbutane was heated for 4 hr at 120° under nitrogen in a 110-ml stainless-steel bomb. The solvent was then stripped and the residue was analyzed by gas chromatography. The results shown in Table V are averages of two runs. The gas chromatographic analyses were carried out on an F & M Model 500 temperature-programmed instrument. A 12-ft stainless steel column packed with UCON 75H on Chromosorb W was used. The initial column temperature was 100°, and this was raised to 200° at a rate of 11°/min. The fact that the two primary isomers were obtained in the expected 2:1 ratio was a good check on the analytical procedure.

# A Fluorine Nuclear Magnetic Resonance Shielding Study of Substituent Effects on $\pi$ -Charge Distributions in Benzophenone and Its Lewis Acid Adducts<sup>1a</sup>

R. G. Pews, Y. Tsuno, and R. W. Taft<sup>1b</sup>

Contribution from the Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania. Received December 3, 1966

**Abstract:** Fluorine nuclear magnetic resonance (F nmr) shielding has been investigated for an extensive series of *ortho*-*m'*- and *p'*-substituted benzophenones and their Lewis acid complexes in methylene chloride solution. This study appears to be the first systematic study of substituent nmr shielding effects in both the reactant and the product of a chemical reaction under common conditions. The *p*-fluorophenyl label is used to measure  $\pi$ -charge density at the carbonyl carbon atom. It is concluded that the change in  $\pi$ -charge density at the carbonyl carbon induced by the polar effect of the *m'*- or *p'*-substituted phenyl group is directly proportional to the product of the  $\sigma$  of the substituent and the carbonyl carbon atom charge density in the unsubstituted derivative. This result gives strong support for the hypothesis of Hammett.

Substituent effects on fluorine nuclear magnetic resonance shielding (F nmr) in *para*-substituted benzophenones have been related to the changes in charge density at the fluorine atom and its carbon atom.<sup>2</sup> HMO calculations further approximately linear relationships in *p*-fluoro-derivatives, *p*-FC<sub>6</sub>H<sub>4</sub>COX, between the  $\pi$ -densities at the carbonyl carbon and *p*-fluoro-carbon atom.<sup>3</sup> The expected consequence of these relationships is that F nmr shielding in the *p*-fluorophenyl label may be utilized to measure changes on charge density which occur at the carbonyl carbon atom.

Similar effects of *meta*- and *para*-substituted groups on chemical reactivities follow with high precision the modified  $\sigma\rho$  relationship.<sup>4</sup> These effects are encountered when the measured effects arise from direct conjugation. Hammett supposed that the quantity  $-\sigma$  measures the change in reactivity produced by the substituent at the reaction center.<sup>5</sup> In this paper we have subjected the Hammett hypothesis to direct test in the following

shielding in an extensive series of *p*-fluoro-*m'*-substituted benzophenones (structure I) and their Lewis acid complexes has been determined.

In this series, the polar effects of the *m'*- and *p'*-substituted phenyl groups on the F nmr shielding are to follow the  $\sigma^0\rho$  relationship,<sup>4</sup> confirming

the work was performed at the Pennsylvania State University in part by the Office of Naval Research is gratefully acknowledged. (b) Department of Chemistry, University of California.

Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., New York, N. Y., 1940, p 196.

the Hammett hypothesis. The values of  $\rho$  for the uncomplexed ketone and for several Lewis acid adducts have been determined by the procedure of Taft and Lewis.<sup>6</sup> A direct relationship is found between the  $\rho$  values and the  $\pi$ -electron density at the carbonyl carbon atom of unsubstituted *p*-fluorobenzophenone and its adducts. The relationship bears an analogy to Hine's  $\tau$  relationship.<sup>7</sup> The results have important application to substituent effects on the thermodynamic properties for formation of the Lewis acid adducts of I. This is the subject of the following companion paper.

F nmr shielding in the formation of 1:1 adducts of BF<sub>3</sub>, BCl<sub>3</sub>, and BBr<sub>3</sub> with *p*-fluorophenyl-labeled bases has been found to be ideal for the present objectives. Thus the shielding parameters of both uncomplexed base and the 1:1 adduct are obtained in a common pure solvent (CH<sub>2</sub>Cl<sub>2</sub>). The shielding for the adduct is found to involve little or no medium effect. In the present work results similar to that previously obtained with *p*-fluorobenzonitrile<sup>8</sup> have been found for the *p*-fluorobenzophenones, I. At room temperatures the adducts are rapidly dissociated giving rise to a single time-average fluorine signal. The signal is the weighted average of the shielding parameters for complexed and uncomplexed base.<sup>9</sup> The observed shieldings for a series of methylene chloride solutions having an approximately constant concentration ( $\sim 0.4$  M) of the *p*-fluorobenzophenone, and increasing concentrations of Lewis acid display a limiting downfield shift at a stoichiometric acid-base ratio of unity (cf. Figure 2 of ref 8 as a typical result). With the weaker acids or bases employed in this study an acid-base ratio of 3-10 is required to obtain the limiting shift (the shielding parameter for the adduct).

The proton adducts of compounds such as series I ketones have F nmr shieldings which are highly medium sensitive.<sup>10</sup> It is, therefore, impossible to obtain the

shielding parameters for the proton adducts and the uncomplexed ketones in a common solvent. In this work we have obtained the shielding parameters of the protonated forms of I as they occur in 99.8% (wt)  $\text{H}_2\text{SO}_4$  containing the ketone ( $\sim 0.4 M$ ).

### Experimental Section

**Preparation of *m*- and *p*-Fluorobenzophenones.** *p*-Fluorobenzophenone. To a solution of 5 g of benzoyl chloride and 10 ml of fluorobenzene in 25 ml of carbon disulfide, 6 g of  $\text{AlCl}_3$  was added in several portions with stirring. Stirring was continued for 3 hr and then the mixture was warmed on a steam bath for 1 hr. The solvent was removed and the residue decomposed with ice and hydrochloric acid. The oily product was extracted with ether and washed with aqueous sodium hydroxide solution and water. The ether was evaporated and the residue purified through an alumina column. Recrystallizations from petroleum ether gave 5.5 g of the ketone (mp 49–50°, lit.<sup>11</sup> mp 48.2–48.7°).

*m*-Fluorobenzophenone. This ketone was obtained by the condensation of 4 g of *m*-fluorobenzoyl chloride with benzene in carbon disulfide solution in the presence of  $\text{AlCl}_3$ . The product was recrystallized from petroleum ether (mp 54.5–55°, lit.<sup>12</sup> mp 55°).

The following ketones were prepared in the same manner from fluorobenzene and the correspondingly substituted benzoyl chlorides. The products were purified by repeated recrystallizations from aqueous ethanol, ethanol, and petroleum ether: *p,p'*-difluorobenzophenone (mp 107°, lit. mp 106–107°, 11 107.5–108.5°), *m,p'*-difluorobenzophenone (mp 61.0–61.5°), *p*-fluoro-*m'*-chlorobenzophenone (mp 77.5–78°), *p*-fluoro-*m'*-trifluoromethylbenzophenone (mp 45–46°), *p*-fluoro-*p'*-trifluoromethylbenzophenone (mp 100.5–101.5°), *p*-fluoro-*p'*-nitrobenzophenone (mp 88–88.5°), *p*-fluoro-*m'*-bromobenzophenone (mp 84.5°).

*p*-Methoxy-*p'*-fluorobenzophenone. To a solution of 18 g of anisole and 15 g of *p*-fluorobenzoyl chloride in 75 ml of carbon disulfide, 15 g of  $\text{AlCl}_3$  was added dropwise under moderate refluxing. After standing for 2 hr at room temperature the solvent was removed and the residue decomposed with hydrochloric acid and ice. The resulting mixture was heated on a steam bath for 1 hr and the crystalline product collected on a filter and washed with water. The product was purified by recrystallizations from ethanol (mp 97–97.5°, lit. mp 94.5–95.5°, 14 96.0–96.5°).

Figure 2. Polar effects of 3' and 4' substituents and conjugation effects of 4' substituents in *p*-fluorobenzophenones and their  $\text{BCl}_3$  adducts on fluorine nuclear magnetic resonance shielding.

*p*-Methoxy-*m'*-fluorobenzophenone was obtained in the same way from *m*-fluorobenzoyl chloride and recrystallized from aqueous ethanol and ethanol (mp 69.5–70°).

The following ketones were prepared similarly by the Friedel-Crafts reaction of *m*- or *p*-fluorobenzoyl chloride with substituted benzenes in carbon disulfide solution. The products were purified by repeated recrystallizations from aqueous ethanol, ethanol, and petroleum ether: *p*-methyl-*p'*-fluorobenzophenone (mp 97.5–98°, lit.<sup>13</sup> mp 98–99°) and *p*-methyl-*m'*-fluorobenzophenone (mp 53–54°) were obtained from toluene; *p*-ethyl-*p'*-fluorobenzophenone (mp 69.5–70°) and *p*-ethyl-*m'*-fluorobenzophenone [bp 139–141° (2 mm)] from ethylbenzene; *p*-butyl-*p'*-fluorobenzophenone (mp 75–75.5°) and *p*-*t*-butyl-*m'*-fluorobenzophenone (mp 30–31°) from *t*-butylbenzene; *p*-chloro-*p'*-fluoro- (mp 113–114°, lit.<sup>14</sup> mp 115°) and *p*-chloro-*m'*-fluorobenzophenone (mp 79.5–80°) from chlorobenzene; *p*-bromo-*p'*-fluorobenzophenone (mp 108.5–109°, lit.<sup>14</sup> mp 107–108°) and *p*-bromo-*m'*-fluorobenzophenone (mp 87–88°) from bromobenzene in poor yields; *p*-ethoxy-*p'*-fluorobenzophenone (mp 87.5–88°, lit.<sup>13</sup> mp 86.5–87.5°) and *p*-ethoxy-*m'*-fluorobenzophenone [bp 176° (4 mm)] from phenyl ethyl ether; *p*-phenoxy-*p'*-fluorobenzophenone (mp 101.5–102°) and *p*-phenoxy-*m'*-fluorobenzophenone (mp 61–62°) from diphenyl ether; *p*-thiomethyl-*p'*-fluorobenzophenone (mp 105–106°, lit.<sup>14</sup> mp 105.5–106.5°) and *p*-thiomethyl-*m'*-fluorobenzophenone (mp 78–79°) from thioanisole; *p*-phenyl-*p'*-fluorobenzophenone (mp 148.5–149°) and *p*-phenyl-*m'*-fluorobenzophenone (mp 104–105°) from biphenyl.

*m*-Methyl-*m'*-fluorobenzophenone. To a Grignard solution prepared from 14 g of *m*-fluorobromobenzene and 2.2 g of magnesium, 9 g of *m*-methylbenzotrile diluted with an equal amount of ether was added dropwise under cooling in ice-salt bath. The reaction mixture was allowed to stand overnight, warmed under gentle reflux for 1 hr and decomposed with ice and hydrochloric acid. The aqueous mixture was heated on a steam bath for 1 hr and left overnight. The organic material was dissolved in ether, washed with aqueous sodium hydroxide solution, dilute hydrochloric acid, and water, and dried over calcium chloride. Distillation yielded 12 g of the ketone [bp 130–130.5° at (2 mm)].

*m*-Methyl-*p'*-fluorobenzophenone was prepared in the same way. A center fraction, 137–139° (2 mm), was recrystallized from petroleum ether (mp 46.5–47°).

(15) W. Funasaka, T. Ando, K. Kondo, and S. Kodama, *Yuki Gosei Kagaku Kyokai Shi*, **17**, 717 (1959).

ifluoromethyl-*m*'-fluorobenzophenone (mp 37–38°) and bromomethyl-*p*'-fluorobenzophenone (mp 45–46°) were obtained by the reaction of *m*-trifluoromethylbenzoyl chloride with the reagents of the corresponding fluorobromobenzenes. Chloro-*m*'-fluorobenzophenone. A Grignard solution prepared from 15 g of *m*-fluorobromobenzene in 30 ml of ether was slowly (1 hr) to a cold solution of *m*-chlorobenzoyl chloride, 125 ml of ether. After addition of the reagent, the mixture was allowed to stand overnight at room temperature. The mixture was refluxed for 0.5 hr and decomposed with ice and hydrochloric acid. The aqueous mixture was heated on a steam bath for 1 hr. The organic layer was taken up with ether and washed with aqueous sodium hydroxide, and water. After drying over calcium chloride, the ether was removed, and the resulting product was dissolved in alcohol and precipitated by adding water. Three crystallizations from light petroleum gave 11 g of the ketone (5–62°).

The same procedure was applied for the preparations of *m,m'*-difluorobenzophenone (mp 58.5–59°, recrystallization from petroleum ether), *m*-bromo-*m*'-fluorobenzophenone from *m*-bromochloride (67–67.5°, recrystallization from aqueous ethanol, light petroleum ether mixture), and *p*-trifluoromethyl-*m*-fluorobenzophenone from *p*-trifluoromethylbenzoyl chloride (mp 56° from aqueous ethanol and petroleum ether).

Samples of the ketones which were used to prepare the Lewis acid adducts were sublimed and stored in a desiccator.

**Acids.** Commercial samples of BF<sub>3</sub>, BCl<sub>3</sub>, and BBr<sub>3</sub> were purified by trap-to-trap distillation on the vacuum line. Appropriate baths were used in the traps until a fraction was obtained with the following pressure: BF<sub>3</sub>, 290 mm (–112°); BCl<sub>3</sub>, 470 mm (0°); BBr<sub>3</sub>, 14 mm (20°). AlCl<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> and AlCl<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub> were purchased from Texas Alkyls Inc. and were distilled before use. Purified samples of AlCl<sub>3</sub> and BI<sub>3</sub> were kindly supplied by Mr. J. W.

**Preparation of Nmr Samples.** All solutions were prepared on a vacuum line at 10<sup>–5</sup> mm in the general manner indicated earlier.<sup>8</sup>

Figure 1 pictures the vacuum line scheme. The essentially nonvolatilizing fluorobenzophenones were weighed into a small capillary tube which was sealed in the nmr tube and evacuated to ~10<sup>–6</sup> mm. The BF<sub>3</sub>, BCl<sub>3</sub>, or BBr<sub>3</sub>, the nmr reference (TCTFCB),<sup>16</sup> and the (CH<sub>2</sub>Cl)<sub>2</sub> were measured quantitatively as vapors from constant-volume manometers. Transfer from the manometer was made through appropriate Hg float valves into the U trap subsequently into the nmr tube by means of a liquid N<sub>2</sub> bath. Highly volatile acids [BI<sub>3</sub>, AlCl<sub>3</sub>, AlCl<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>, and AlCl<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>] were protected from contact with air and moisture by the magnetic breaker seals. The breakers were filled with the intimate amount of acid required in a separate operation and in a tube and attached to the line. After evacuation, the seal was broken and the acid transferred from the breaker seal to trap and finally into the nmr tube with the benzophenone. The weight of acid was determined by weighing the breaker seal and after the sample preparation. Solvent and nmr reference were transferred subsequently as described above. In every prepared nmr tube was sealed off under vacuum and stored in liquid N<sub>2</sub> until its spectra were obtained at 25 ± 1°. In each solution displayed a single *p*-fluorophenyl signal. The procedure used in preparing the samples of uncomplexed ketone and the H<sub>2</sub>SO<sub>4</sub> solutions<sup>17</sup> is that described earlier. The procedure followed in obtaining the shielding parameters also has been previously described.<sup>16</sup>

is

Table I are listed the shielding parameters (relative to internal fluorobenzene),  $\int_H^{p-X_a}$ , for a series of

acid adducts of *p*-fluorobenzophenone in methylene chloride solution at 25°. The shielding parameters have been obtained from at least three separate experiments with stoichiometric acid to base ratio (*a/b*) of 5. The limiting shifts from these experiments decrease to ±0.08 ppm. For the uncomplexed ketone the precision is ±0.03 ppm. The BF<sub>3</sub> and AlCl<sub>3</sub>

**Table I.** Fluorine Nmr Shielding Parameters for Lewis Acid Adducts of *p*-Fluorobenzophenone

Acid	$\int_H^{p-X_a}$ , ppm	Acid	$\int_H^{p-X_a}$ , ppm
None (uncomplexed)	6.69	AlCl <sub>3</sub> (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub>	21.77
AlCl <sub>3</sub> (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub>	17.20	AlCl <sub>3</sub>	22.40
BF <sub>3</sub>	17.62	BBr <sub>3</sub>	22.85
BCl <sub>3</sub>	21.20	BI <sub>3</sub>	23.62

(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> results are about 0.3 ppm upfield from the limiting value at *a/b* = 1, presumably because of a small amount of dissociation. For these, the limiting shift was obtained at *a/b* = 3–5. A titration curve for BF<sub>3</sub> (*a/b* = 0.17–5.3) gave results similar to those reported with *p*-fluorobenzonitrile.<sup>8</sup> Analysis by the Ehrenson computer program<sup>18</sup> gave the limiting shift indicated and a dissociation equilibrium constant (in *M* units) *K*<sub>D</sub> = 0.004 ± 0.002.

Table II lists the 3'- and 4'-polar substituent shielding effects for the *p*-fluorobenzophenone and its BF<sub>3</sub>, BCl<sub>3</sub>, BBr<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> adducts. All except the latter were obtained in methylene chloride solution at 25°. The latter are from measurements in 99.8% H<sub>2</sub>SO<sub>4</sub>. The symbol Δδ represents the shielding relative to the unsubstituted *p*-fluorobenzophenone derivative. For the methylene chloride solutions, the shielding parameter relative to internal fluorobenzene may be obtained,

of course, by combining  $\left(\int_H^{p-X} = \int_H^{p-X_a} + \Delta\delta\right)$

the results of Tables I and II.

The shielding parameters for the BF<sub>3</sub> adducts given in Table II were obtained utilizing the Ehrenson computer program to analyze for each ketone the results of five to seven experiments with *a/b* = 0.3 to 8.0. For the *p*-CF<sub>3</sub> substituent, for example, this analysis gave Δδ = –3.60 ppm and *K*<sub>D</sub> = 0.018 ± 0.008. This may be compared with Δδ = –3.52 ppm observed in an experiment with *a/b* = 7.71. The values for *K*<sub>D</sub> obtained for the other BF<sub>3</sub> adducts of Table II were within the range 0.002–0.02.

The shielding parameters for the BCl<sub>3</sub> and BBr<sub>3</sub> adducts given in Table II are the limiting shifts obtained from two or three experiments with *a/b* = 3–7. The precision is approximately ±0.08 ppm for each. The precision of the H<sub>2</sub>SO<sub>4</sub> results is comparable.

Table III lists the shielding effects of conjugating *p*' substituents for *p*-fluorobenzophenone and its BF<sub>3</sub>, BCl<sub>3</sub>, BBr<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> adducts under the same conditions as for the corresponding results in Table II. The shielding parameters for the BF<sub>3</sub>, BCl<sub>3</sub>, and BBr<sub>3</sub> adducts were obtained as the limiting shifts for two or three experiments with *a/b* = 1 to 4. The precision is ±0.08 ppm.

Table IV lists the shielding effects of *m*' and *p*' substituents for *m*-fluorobenzophenone in benzene and H<sub>2</sub>SO<sub>4</sub> solutions. For comparison the corresponding *p*-fluorobenzophenone shielding effects are also shown. It is apparent from Table IV that *p*-F shielding effects in the uncomplexed ketone are uniformly about threefold greater than for corresponding *m*-F shielding effects. A substantial number of similar results were

obtained previously.<sup>19</sup> In the proton adducts in H<sub>2</sub>SO<sub>4</sub> it is also apparent that this factor increases to about 5.5 for polar substituent effects. For conjugat-

(19) R. W. Taft, E. Price, I. R. Fox, I. C. Lewis, K. K. Andersen, and G. T. Davis, *J. Am. Chem. Soc.*, **85**, 3146 (1963).

ing *p'* substituents the factor increases further to approximately ninefold (cf. following discussion, in particular concerning eq 5).

### Discussion

Theoretical treatments of substituent effects on fluorine shielding in *meta*- and *para*-substituted fluorobenzene have given the relationship<sup>20</sup>

$$\int_H^{p-X} = C_1 \Delta q_F + C_2 \Delta p_{C-F} + C_3 \Delta I \quad (1)$$

where  $\int_H^{p-X}$  is the shielding parameter for the *para*-substituted fluorobenzene relative to internal fluorobenzene,  $\Delta q_F$  is the change (relative to C<sub>6</sub>H<sub>5</sub>F) in  $\pi$ -electron charge density at the fluorine atom,  $\Delta p_{C-F}$  is the change in the C-F  $\pi$ -bond order,  $\Delta I$  is the change in ionic character of the C-F  $\sigma$  bond which is induced by the polar substituent, and  $C_1$ ,  $C_2$ , and  $C_3$  are constants. By using the shielding of the *para*-substituted fluorobenzene relative to that of its *meta* isomer,  $\int_{m-X}^{p-X}$ ,

(20) (a) M. Karplus and T. P. Das, *J. Chem. Phys.*, **34**, 1683 (1961); (b) F. Prosser and L. Goodman, *ibid.*, **38**, 374 (1963).

term very generally vanishes for most practical cases. Further, HMO theory anticipates linear relationships between corresponding values of  $\Delta q_F$ ,  $\Delta q_{C-F}$ , and  $\Delta q_{C-O}$ , where the latter is the change (relative to benzene carbon, the substituent effect of X and to produce uniformly a sevenfold greater  $\pi$ -charge density at the carbonyl carbon than at the *para* carbon atom.<sup>3</sup> This result is quite generally for *p*-fluorobenzoyl derivatives

$$\int_{m-X}^{p-X} = C_4 \Delta q_{C-F} \quad (2)$$

constant  $C_4$  is estimated from experimental results 120 ppm/e.<sup>19</sup>

Simple model HMO calculations for *p*-fluorobenzoyl derivatives, *p*-FC<sub>6</sub>H<sub>4</sub>COX, where X is a carbonyl atom of Coulomb integral  $-0.5$  to  $+2.0$   $\beta$  relative to benzene carbon, the substituent effect of X tends to produce uniformly a sevenfold greater  $\pi$ -charge density at the carbonyl carbon than at the *para* carbon atom.<sup>3</sup> This result is quite generally for *p*-fluorobenzoyl derivatives

$$\Delta q_{C-F} = C_5 q_{C-O} + C_6 \quad (3)$$

$q_{C-O}$  is the  $\pi$ -charge density at the carbonyl carbon, and  $C_5$  and  $C_6$  are constants. Combination of eqs 2 and 3 indicates that the *p*-fluorophenyl label is used to study the  $\pi$ -electron density changes at the carbonyl carbon, *i.e.*

$$\Delta \int_{m-X}^{p-X} = C_7 \Delta q_{C-O} \quad (4)$$

$C_7 \cong 40$  ppm/e. Equation 4 may be simplified by the present experimental investigation. It has been shown<sup>19</sup> experimentally that for restricted families of similar substituents, such as the ketone series I or Lewis acid adducts (*cf.* Table IV and comments), the following relationships hold.

$$\Delta \int_H^{p-X} = C_8 \Delta \int_H^{m-X} \quad (5)$$

$$\Delta \int_{m-X}^{p-X} = [(C_8 - 1)/C_8] \Delta \int_H^{p-X}$$

$C_8$  is a constant. Combining eq 4 and 5 gives

$$\Delta \int_H^{p-X} = C_9 \Delta q_{C-O} \quad (6)$$

$\Delta \int_H^{p-X}$  refers to the shielding of a *p*'-substituted *p*-fluorobenzophenone (or acid adduct) relative to unsubstituted *p*-fluorobenzophenone (or adduct), and  $C_9$  is the corresponding change in the  $\pi$ -charge density at the carbonyl carbon, and  $C_9$  [ $= C_8 C_7 / (C_8 - 1)$ ] is a constant.

Interpretation of the *meta*- and *para*-substituent effects on rates and equilibria for side-chain derivatives which are described by the  $\sigma\rho$  relationship, Hammett<sup>5</sup> supposed that the quantity  $-\sigma$  measures the change in charge density produced by the substituent at the side-chain reaction center, *i.e.*, for example, for I ketones  $\Delta q_{CO} \propto (-\sigma)$ . By the application of  $^{19}F$  nmr shielding in series I ketones and their acid adducts, it follows that the Hammett hypothesis is satisfied by the relationship

$$\Delta \int_H^{p-X} = -\bar{\rho}\sigma \quad (7)$$

where  $\rho$  is used to distinguish the shielding series constant for a given series of ketone derivatives from the usual reactivity series constant,  $\rho$ .

In Figure 2 are plotted  $\Delta \int_H^{p-X}$  values from Tables III and IV for *m*'- and *p*'-substituted *p*-fluorobenzophenones and their BCl<sub>3</sub> adducts *vs.*  $\sigma^0$  values.<sup>4</sup> In general, a linear trend is clearly discernible. Linear relationships of excellent precision, however, encompass only the *m*' and nonconjugating *p*' substituents. The crossed-circle points for *p*' substituents represent significant deviations from eq 7 according to the criterion of Taft and Lewis.<sup>6</sup> The results in Figure 2 have the same characteristics, for example, as a plot of Brown's  $\sigma^+$  values<sup>21</sup> *vs.*  $\sigma^0$ . We conclude that Hammett's hypothesis is confirmed for the polar effects of *m*' and *p*' substituents.

The additional effects of direct conjugation between  $-R$  *p*' substituents and the carbonyl group lead to deviations from eq 7 as might be expected by Brown's  $\sigma^+$  treatment.<sup>21</sup> The latter parameters, however, do not generally suffice quantitatively to describe the observed combination of polar and conjugative effects. This result is seen by comparison of corresponding  $\sigma^+$  values and the "effective"  $\bar{\sigma}^+$  ( $\equiv \Delta \int_H^{p-X} / \bar{\rho}$ ) values

which are listed in Table III for conjugating *p*' substituents. For *p*'-OCH<sub>3</sub> and *p*'-SCH<sub>3</sub>, the  $\bar{\sigma}^+$  values for uncomplexed ketone and for the BF<sub>3</sub>, BCl<sub>3</sub>, and BBr<sub>3</sub> adducts are significantly less negative than Brown's  $\sigma^+$  values. In H<sub>2</sub>SO<sub>4</sub>, however, the  $\bar{\sigma}^+$  for these two substituents are significantly more negative than Brown's  $\sigma^+$  values. For all of the *p*' substituents of Table III the  $\bar{\sigma}^+$  value of the uncomplexed ketone is substantially less than Brown's  $\sigma^+$  value. On the other hand, Brown's  $\sigma^+$  values for *p*-OC<sub>6</sub>H<sub>5</sub>, *p*-CH<sub>3</sub>, *p*-C<sub>2</sub>H<sub>5</sub>, *p*-*t*-C<sub>4</sub>H<sub>9</sub>, and *p*-Cl apply quite satisfactorily for all of the Lewis acid adducts of Table III.

In Hine's  $\tau$  relationship<sup>7</sup> the reaction constant,  $\rho$ , for polar reactivity effects of *meta* and *para* substituents is directly related to the change in the  $\sigma$  value of the side-chain reaction center. Thus the Hammett and the Hine hypotheses suggest that the  $\pi$ -charge density of the carbonyl carbon of the unsubstituted ketone derivative determines the susceptibility of this center to changes in charge density produced by substituent polar effects. This condition and eq 2, 3, and 5 lead to the relationship

$$-\bar{\sigma}^+ = \int_H^{p-X} / k \quad (8)$$

where  $\int_H^{p-X}$  is the shielding of the unsubstituted *p*-fluorobenzophenone derivative relative to internal fluorobenzenes (Table I) and  $k$  is a constant for a series of carbonyl derivatives.

Equation 8 is confirmed by the excellent agreement between  $\Delta \int_{\text{exptl}}^{p-X}$  and  $\Delta \int_{\text{calcd}}^{p-X}$  values given in Table II

(21) H. C. Brown and Y. Okamoto, *J. Am. Chem. Soc.*, **79**, 1913 (1957); **80**, 4979 (1958).

for the uncomplexed ketones and their  $\text{BF}_3$ ,  $\text{BCl}_3$ , and  $\text{BBr}_3$  adducts;  $\Delta \int_{\text{H}}^{\text{p-X}} \text{ is obtained as } \left( \int_{\text{H}}^{\text{p-X}_0} / 2.75 \right)$ . ( $-\sigma^0$ ), i.e.,  $k = 2.75$ . The generality and precision of eq 8 (which is illustrated in Table II) indicates that this relationship may be used reliably to predict  $\int_{\text{H}}^{\text{p-X}}$  values for the other Lewis acid adducts of Table I with additional well-behaved polar substituents of known  $\sigma^0$  value. For these, the shielding of  $m'$ - and  $p'$ -substituted  $p$ -fluorobenzophenone derivatives relative to fluorobenzene is given by

$$\int_{\text{H}(\text{calcd})}^{\text{p-X}} = \int_{\text{H}(\text{obsd})}^{\text{p-X}_0} + \sigma^0 \rho = \int_{\text{H}}^{\text{p-X}_0} \left( 1 + \frac{\sigma^0}{2.75} \right) \quad (9)$$

The corresponding relationship for  $\pi$ -charge density given by eq 4 is

$$q_{\text{CO}} = q^0_{\text{CO}} [1 + (\sigma^0/2.75)] \quad (10)$$

where  $q^0_{\text{CO}}$  is the carbonyl carbon  $\pi$ -charge density in unsubstituted  $p$ -fluorobenzophenone.

Using the relationships established previously between  $\sigma$  values and F nmr substituent shielding effects in *meta*- and *para*-substituted fluorobenzenes, the present results may be used to calculate the  $\sigma$  values for the  $\text{COC}_6\text{H}_5$ ,  $\text{CO}(\text{BF}_3)\text{C}_6\text{H}_5$ , and  $\text{CO}(\text{BCl}_3)\text{C}_6\text{H}_5$  substituents.<sup>16,19</sup>

$$\sigma_{(\text{p})} = \sigma_{\text{I}} + \sigma_{\text{R}} \quad (11)$$

$$\int_{\text{m-X}}^{\text{p-X}} = -29.5 \sigma_{\text{R}} \quad (12)$$

$$\int_{\text{H}}^{\text{m-X}} = -7.1 \sigma_{\text{I}} + 0.6 \quad (13)$$

In methylene chloride solutions, the additional shielding parameters have been obtained for *m*-fluorobenzophenone ( $\int_{\text{H}}^{\text{m-X}} = -0.81$  ppm), its  $\text{BF}_3$  adduct ( $\int_{\text{H}}^{\text{m-X}} = -2.88$  ppm), and its  $\text{BCl}_3$  adduct ( $\int_{\text{H}}^{\text{m-X}} = -3.81$  ppm). These shieldings and the

corresponding  $p$ -fluorobenzophenone results (Table I) yield the  $\sigma$  values listed in Table V. It is further illustrated by the  $\bar{\rho}/6.3$  values given in Table V that the  $\bar{\rho}$  values of Table II are essentially directly proportional to the  $\sigma_{(\text{p})}$  values as required by the discussion above.

Table V.  $\sigma$  Values from F Nmr Shielding Results

Substituent	$\sigma_{\text{I}}$	$\sigma_{\text{R}}$	$\sigma_{(\text{p})}$	$\bar{\rho}/6.3$	$\Delta\sigma_{(\text{p})}$
$\begin{array}{c} \text{O} \\ \parallel \\ -\text{C} \\ \diagup \\ \text{C}_6\text{H}_5 \end{array}$	+0.20	+0.20	0.40	0.39	...
$\begin{array}{c} \text{O} \\ \parallel \\ -\text{C} \\ \diagup \\ \text{C}_6\text{H}_5 \\ \text{O-BF}_3 \end{array}$	+0.49	+0.50	0.99	1.02	0.59
$\begin{array}{c} \text{O} \\ \parallel \\ -\text{C} \\ \diagup \\ \text{C}_6\text{H}_5 \\ \text{O-BCl}_3 \end{array}$	+0.62	+0.59	1.21	1.22	0.81

It is clear from these results, eq 6, and  $\Delta \int_{\text{H}}^{\text{p-X}}$  values for uncomplexed and complexed ketones (Tables II and III) that the change in  $\sigma$  value or charge density for the carbonyl functional group on formation of a Lewis acid adduct is *not* independent of the 3' or 4' substituent. However, by consideration of eq 10: for the carbonyl carbon of the uncomplexed ketone,  $q_{(\text{u})} = q^0_{(\text{u})} [1 + (\sigma^0/2.75)]$ ; for the carbonyl carbon of the complex,  $q_{(\text{c})} = q^0_{(\text{c})} [1 + (\sigma^0/2.75)]$ . Therefore, for formation of the complex,  $\Delta q = q_{(\text{c})} - q_{(\text{u})} = \Delta q^0 [1 + (\sigma^0/2.75)]$ . Thus, for the substituent effect on formation of the complex,  $\Delta q - \Delta q_0 = \Delta q^0 (\sigma^0/2.75) \propto (\Delta\sigma_{\text{R}}) \sigma^0_{\text{X}}$ , where  $\Delta\sigma_{\text{R}}$  = the change in  $\sigma_{(\text{p})}$  value for the unsubstituted functional group (*cf.* Table V) and  $\sigma^0_{\text{X}}$  is the  $\sigma$  value for the 3'- or 4'-polar substituent. Further consideration of matters relevant to complex formation is given in the following companion paper.

# Evaluation of Ground-State Electronic Energy from Fluorine Nuclear Magnetic Resonance Shielding. I. Prediction of Enthalpies of Reaction for Formation of Lewis Acid Adducts of Benzophenones<sup>1</sup>

C. S. Giam and R. W. Taft

Contribution from the Department of Chemistry, University of California, Irvine, California 92640. Received December 3, 1966

**Abstract:** The previously proposed linear fluorine nuclear magnetic resonance shielding electronic energy (SEE) relationship for *p*-fluorophenyl derivatives is shown to provide satisfactory prediction of the standard enthalpy of reactions of *m*'- and *p*'-substituted *p*-fluorobenzophenones with the Lewis acids BCl<sub>3</sub> and BBr<sub>3</sub>. This result indicates that *p*-fluorophenyl shielding in appropriate systems provides to useful approximation the evaluation of the ground-state electronic energy change needed for *a priori* prediction of rather complex organic equilibria from spectroscopic data. Using Arnett's calorimetric procedure, standard enthalpies of reaction have been measured for the formation of a substantial series of the Lewis acid adducts in methylene chloride. The observed values, ranging from -11.5 to -20.6 kcal/mole, are in good agreement with the predicted values. The linear SEE relationship has been used to obtain a novel analysis of the contributions of substituent perturbations in reactant and product states to the observed thermodynamic substituent effects.

a previous paper,<sup>2</sup> it was proposed that substituent effects on fluorine nuclear magnetic resonance (nmr) shielding in related *p*-fluorophenyl derivatives linear with the substituent effect on the corresponding standard electronic energy change. This relationship

has a theoretical basis in linear relationships between conjugative substituent effects on: (a) *p*-fluorophenyl nmr shielding, (b) the LCAO-MO theory of large density at the *para* carbon atom (bonded to (c) the molecular ionization potential.<sup>2</sup>

The proposed linear shielding electronic energy (SEE) relationship has been confirmed experimentally for the large substituent effects involved in the oxidation of xarylethanes to 4,4''-disubstituted *p*-fluorotriphenylethyl (*p*-fluorotriptyl) cations<sup>2</sup> and in their reduction of 3'- and 4'-substituted *p*-fluorotriptyl anions.<sup>3</sup> The substituent effects on the standard free energy change of these processes are taken to be close estimates of the corresponding electronic energy effects.<sup>2,3</sup> The mean value of the energy-shielding coefficient obtained from the two reaction series is 1.0 kcal/mole ppm,<sup>2,3</sup> in accord with the order of magnitude value anticipated by the theory.<sup>2</sup>

The formation of complexes with strong Lewis acids, such as BCl<sub>3</sub>, is a reaction which has been investigated in detail.<sup>4</sup> The standard enthalpy of adduct formation apparently may be taken as a satisfactory estimator of the standard electronic energy change.<sup>4</sup> In reaction 1, the formation of BCl<sub>3</sub> and BBr<sub>3</sub> adducts of 3'- and 4'-substituted *p*-fluorobenzophenones (series I ketones) presents a close analogy to the formation of the above mentioned *p*-fluorotriptyl cations.

In the companion paper<sup>5</sup> the shielding parameters for series I ketones and their Lewis acid adduct in methylene chloride solution (relative to internal fluorobenzene) are reported. In this paper we report the determination of the standard enthalpies of adduct formation of series I ketones in methylene chloride solution using the calorimetric procedure recently described by Arnett.<sup>6</sup> The predicted values of the enthalpies of complex formation obtained from the linear SEE relationship are found to be in quite satisfactory agreement with the experimental values. A novel analysis of the origin of the substituent effects on the standard enthalpies of reaction 1 has been obtained from the shielding parameters for series I ketones and their Lewis acid adducts through the use of linear SEE relationship.

## Experimental Section

**Materials.** Cf. ref 5.

**Procedure.** The calorimeter used was essentially that described by Arnett, *et al.*,<sup>6</sup> and was purchased from the Guild Corp., Bethel Park, Pa. A Leeds and Northrup Model 8687 potentiometer and a Model 153 Honeywell 1-mv recorder were utilized.

The calorimeter consisted of a 300-ml dewar flask (4.5 in. deep and 2.5 in. i.d.). It was fitted tightly with a Teflon stopper which held in place in the dewar a 5000-ohm thermistor and a 100-ohm electric heating coil. Additional holes in the stopper were used to accommodate syringe ports and a sealed-glass tubing stirrer with a Teflon blade. The stirrer was driven by a constant speed motor. Plastic insulating tape was wrapped around the seal between the Teflon stopper and the dewar to reduce any heat leakage.

This work was supported in part by the National Science Foundation. A preliminary presentation of this work was made in Abstracts of 49th Canadian Chemical Conference, Saskatoon, June 7, 1966.

(6) E. M. Arnett, W. G. Benrude, J. J. Burke, and P. McDugleby, *ibid.*, **87**, 1541 (1965).

Methylene chloride (210 ml, dried by distilling from  $\text{CaH}_2$ ) was placed in the dewar. In order to minimize hydrolysis of  $\text{BCl}_3$  or  $\text{BBr}_3$ , the dewar was first flushed with dry nitrogen followed by the boron halide and then dry nitrogen. A known volume of  $\text{BCl}_3$  was measured with a gas buret and introduced in the gas washing bottle containing the dry methylene chloride. The resulting solution was then transferred under  $\text{N}_2$  to the dewar. Two or more syringes containing the samples for heat measurements were firmly wedged in the holes in the Teflon stopper so that the injection ends of the syringes were just below the liquid in the dewar.

When equilibrium conditions were established ( $25 \pm 1^\circ$ ), heating curves were taken. Typically, using a heating period of 15 sec with the heater current at 0.1 amp,  $\sim 1\text{-mv}$ , deflection on the recorder was obtained. When two or more successive heating curves did not vary more than 2–3%, samples were introduced for determination of heats of solution or of reaction. Following sample injection, heating curves were again repeated which usually did not vary more than 5% from the initial results.

Reaction heats were determined by successive injections of base into methylene chloride solutions containing on the order of 100-fold excess of the acid. The initial acid concentration was 0.1–0.3 *M*. The base was injected either as pure liquid or solid or a methylene chloride solution. In the former cases, the reaction heats were obtained by correcting for the heat of solution of the base in methylene chloride as measured in separate experiments. Liquid samples were injected by hypodermic-type syringes. Solid samples were placed in polypropylene syringes. The injection ends of these syringes were sliced off and replaced by Teflon plugs in order to obtain a wide opening through which the solid could be forced. In injection of solutions, typically 0.2–1.0 ml of a 0.1–0.3 *M* stock solution of base in methylene chloride was used. The reaction heat obtained in this manner was corrected, if necessary, for the small heat of dilution of the acid solution. After the first or second injection of base into the acid solution, it was found that heats of acceptable precision and reproducibility were obtained (cf. Table I). The result of the first or second injection was generally erratic and was not considered in obtaining the mean value. The  $\Delta H^\circ_{\text{f(exptl)}}$  values of Table I as the mean of a least two (generally 3–5) acceptable values.

## Results

In Table I are listed the standard enthalpies (and their precision measures) of complex formation,  $\Delta H^\circ_{\text{f}}$ , obtained for series I ketones with  $\text{BCl}_3$  and  $\text{BBr}_3$

in methylene chloride solution. Values are also listed for the corresponding change in the F nmr shielding parameter,  $\Delta$ , between complexed and uncomplexed ketone, i.e.,  $\Delta = \int_{\text{H(c)}}^{\text{p-X}} - \int_{\text{H(u)}}^{\text{p-X}} = \int_{\text{H}}^{\text{p-X}} + \Delta f_{\text{(c)}} - \Delta f_{\text{(u)}}$ , where the latter shieldings are as designated and listed in Tables I–III of ref 5. The predicted values of  $\Delta H^\circ_{\text{f}}$  obtained from the linear SEE relationship (eq 7, below) are given also. In general the agreement between calculated and observed values of  $\Delta H^\circ_{\text{f}}$  is within the combined uncertainties. The only exception occurs for the enthalpy figure for the 3'-nitro-*p*-fluorobenzophenone- $\text{BBr}_3$  adduct. With  $\text{BBr}_3$  the precision of  $\Delta H^\circ_{\text{f}}$  was generally poorer than for  $\text{BCl}_3$ , but the deviation in this case is beyond experimental error. In view of the generally satisfactory agreement in Table I, the only suggestion which we can offer for the larger observed than predicted enthalpy change is the possibility that there is a contribution to  $-\Delta H^\circ_{\text{f(obsd)}}$  resulting from interaction of  $\text{BBr}_3$  with the nitro group in the adduct which occurs at the very high acid-base ratio ( $>100$ ) employed in the enthalpy determination.

## Discussion

The proposed linear SEE relationship is expressed by

$$\int_{\text{H}}^{\text{p-X}} = mE^\circ + b' \quad (2)$$

where  $\int_{\text{H}}^{\text{p-X}}$  is the shielding parameter for the *p*-fluorophenyl derivative relative to internal fluorobenzene,  $E^\circ$  is the molecular electronic stabilization energy (cf. subsequent Discussion) and *m* and *b* are constants characteristic of the related series of *p*-fluorophenyl derivatives. For reaction 1 application of eq 2 gives

$$\Delta E^\circ = E^\circ_{\text{(c)}} - E^\circ_{\text{(u)}} =$$

$$m \int_{\text{H(c)}}^{\text{p-X}} - m \int_{\text{H(u)}}^{\text{p-X}} + b = m\Delta + b \quad (3)$$

where  $\Delta$  is the difference in the shielding parameter between complexed and uncomplexed ketone. It is assumed for present purposes that for reaction 1  $\Delta E^\circ \cong \Delta H^\circ_{\text{f}}$  (298°K).

In the present application of eq 3 two types of structural variations are being considered, i.e., variable Lewis acid and variable *m'* and *p'* substituents. With *p*-fluorobenzonitrile it was found<sup>7</sup> (qualitatively) that *m* has positive sign, i.e., increasing  $-\Delta H^\circ_{\text{f}}$  is accompanied by increasing  $-\Delta$ . A similar sign of *m* is expected for the Lewis acid adducts of *p*-fluorobenzophenone. On the other hand, with increased electron withdrawal by the *m'* or *p'* substituent,  $-\Delta$  increases but  $-\Delta H^\circ_{\text{f}}$  decreases (as expected); i.e., *m* has a negative sign for the substituent effect.

Thus the following two relationships are generated from eq 3: for various Lewis acid adducts of *p*-fluorobenzophenone

$$\Delta H^\circ_{\text{f}} = \cong \Delta E^\circ = m\Delta_0 + b \quad (4)$$

and for the substituent effect (relative to unsubstituted *p*-fluorobenzophenone)

$$\int_{\text{R}} \Delta H^\circ_{\text{f}} \cong \int_{\text{R}} \Delta E^\circ = -m \int_{\text{R}} \Delta = m(\Delta_0 - \Delta) \quad (5)$$

(7) R. W. Taft and J. W. Carten, *J. Am. Chem. Soc.*, **86**, 4199(1964).

<sup>a</sup> Calculated from eq 7. <sup>b</sup> Calculated from eq 9 of ref 5 using  $\sigma^+ = -0.49$ .

where  $\Delta$  refers to the substituted fluorobenzophenone and  $\Delta_0$  to unsubstituted *p*-fluorobenzophenone. Combining eq 4 and 5 gives

$$\Delta H^\circ_f = \Delta E^\circ_0 + \int_R \Delta E^\circ = m(2\Delta_0 - \Delta) + b \quad (6)$$

on the assumption that the magnitude of  $m$  is the same (1.00 kcal/ppm; cf. introductory section) for both types of structural dependence.

In order to obtain an independent evaluation of the constant  $b$  in eq 3 we have determined  $\Delta$  and  $\Delta H^\circ_f$  for reaction 1 for the formation of the  $\text{BCl}_3$  adduct of *p*-fluoroacetophenone. We believe the value of  $b$  obtained with the use of the latter ketone will be essentially correct for use with *p*-fluorobenzophenone adducts since acetophenone and benzophenone are of essentially identical base strength.<sup>8</sup> Values of  $\Delta = -18.20 \pm 0.06$  ppm and  $-\Delta H^\circ_f = 18.9 \pm 0.2$  kcal/mole have been obtained with *p*-fluoroacetophenone from which  $b = -0.7$  kcal/mole. Equation 6 may be reduced then to the following simplified explicit form for reaction 1

$$\Delta H^\circ_f = 2\Delta_0 - \Delta - 0.7 \text{ (in kcal/mole)} \quad (7)$$

The success of eq 7 is displayed in Table I in the comparison between observed and predicted values of  $-\Delta H^\circ_f$  for reaction 1. It is to be emphasized that the predictions of eq 7 depend in no way upon the correlations made in the companion paper.<sup>5</sup> Further, the correlation of  $\Delta$  values with  $\sigma^0$  is limited to substituents which involve no direct conjugative effects<sup>5</sup> whereas the confirmed predictions of eq 7 include both strongly conjugating and nonconjugating substituents.

Equation 7 and similar relationships derived from the linear SEE relationship promise to be of great utility in obtaining values of  $\Delta H^\circ_f$  which are difficult or impossible to obtain by direct experimental determination. In our hands,  $\Delta$  has been found generally to be a more precisely and easily measured quantity than  $\Delta H^\circ_f$ .

Equation 7 may be combined with the polar substituent effect relationship,<sup>5</sup>  $\Delta = \Delta_0[1 + (\sigma^0/2.75)]$ , to obtain the (limited) relationship

$$-\Delta H^\circ_f = \Delta_0[\sigma^0/2.75] + 0.7 \quad (8)$$

Equation 8 may be used (where applicable) to calculate  $\Delta H^\circ_f$  values for any of the Lewis acid adducts for the series I ketones for which  $\Delta_0$  (cf. Table I, ref 5 for acids, e.g.,  $\text{AlCl}(\text{C}_2\text{H}_5)_2$ ,  $\text{BI}_3$ , etc.) and  $\sigma^0$  values are available. While these uses of F nmr shielding for predictions of reactivities must be regarded as having substantial consequences, the greatest significance of the linear SEE relationship is probably in the unique extra-thermodynamic analysis of substituent effects on reactivities which it permits.

The electronic stabilization energy which is measured according to eq 2 by the F nmr shielding parameter is extrathermodynamic.<sup>9</sup> That is, in terms of the theoretical models used to derive eq 2 the perturbation on the  $\pi$  electronic energy levels of *p*-fluorobenzophenone is measured but the energy content of the substituent is not included. The relevant changes in  $E^\circ$  may be

approximated (for conceptual purposes) by the following model thermodynamic exchange reactions:

for variable Lewis acid

$$\Delta E^\circ_{(9)} \cong E^\circ_{A_2} - E^\circ_{A_1} = \int_R E^\circ$$

for variable substituent in base

$$\Delta E^\circ_{(10)} \cong E^\circ_{X(u)} - E^\circ_{H(u)} =$$

$$\int_R E^\circ_{(u)} \equiv -(\text{SE})_{(u)} = -\Delta \int_{(u)}$$

for variable substituent in adduct

$$\Delta E^\circ_{(11)} \cong E^\circ_{X(c)} - E^\circ_{H(c)} =$$

$$\int_R E^\circ_{(c)} \equiv -(\text{SE})_{(c)} = -\Delta \int_{(c)}$$

Although values of  $\Delta E^\circ_{(9)}$ ,  $\Delta E^\circ_{(10)}$ , and  $\Delta E^\circ_{(11)}$  represent fundamental quantities, there is little immediate prospect that precise values of these quantities will become available by thermodynamic means.

The thermodynamic substituent effects measured in this investigation,  $\int_R \Delta H^\circ_f$ , correspond to the following reaction.

$$\int_R \Delta H^\circ_{f(1)} = \Delta H^\circ_{f(12)} \cong \Delta E^\circ_{(12)} = (\text{SE})_u - (\text{SE})_c =$$

$$\Delta E^\circ_{(11)} - \Delta E^\circ_{(10)}$$

Values of the substituent stabilization energies (as defined above) for uncomplexed and complexed ketone obtained from the linear SEE relationship therefore permit a novel analysis of the origin of the thermodynamic substituent effects. Specifically, the relative contributions of the substituent perturbations on the reactant and product states of reaction 1 is obtained.

$p'$ - $\text{OC}_6\text{H}_5$	0.45	+3.66	+3.21	+3.3
$p'$ - $i\text{-C}_4\text{H}_9$	0.41	+1.85	+1.44	+1.6
H	(0.00)	(0.00)	(0.00)	(0.0)
$p'$ -Cl	-0.52	-1.05	-0.53	-0.6
$m'$ -F	-0.75	-2.44	-1.69	-1.5
$m'$ -Br	-0.89	-2.80	-1.91	-1.6
$m'$ - $\text{CF}_3$	-1.17	-3.70	-2.53	-2.5
$p'$ - $\text{CF}_3$	-1.32	-4.25	-2.93	-2.8
$m'$ - $\text{NO}_2$	-1.79	-5.33	-3.54	-3.6

The identification of the substituent stabilization energies for uncomplexed and complexed ketone with the quantities  $\Delta f_{(u)}$  and  $\Delta f_{(c)}$ , of course, does involve the assumption that  $m = 1.00$  kcal/mole ppm as found for the  $\Delta E^\circ_{(12)}$  ( $\Delta$ ) process. This assumption is supported by the well-behaved  $\sigma^0\bar{p}$  behavior displayed by both the substituted uncomplexed and complexed ketones<sup>6</sup> and the fact that the range in  $\Delta$  values involved (cf. Table I) of about 10 ppm is of similar order of magnitude as the range of  $\int_H^{p-X}$  values between the uncomplexed  $p'$ - $\text{OCH}_3$  compound and the  $\text{BBR}_3$  complexed  $m'$ - $\text{NO}_2$  compound (about 22 ppm). In view of this and subsequent discussion it is highly unlikely that any errors due to this assumption exceed 20% of the result listed in Table II and smaller error seems probable.

It is clear from the results in Table II that the thermodynamic substituent effects are the resultants of substantial effects in both complexed and uncomplexed ketone, although effects in the former state do predominate. While the substituent effects are qualitatively parallel in both states, there is no fixed factor which quantitatively relates the effects of either state to the observed thermodynamic properties. However, for those substituents which exert only a polar ( $\sigma^0$ ) effect, fixed factors are applicable. These are obtained from the ratios of the  $\bar{p}$  values given in ref 5.

It is apparent from the above discussion and results that the linear SEE relationship provides also the prediction of the reaction constant,  $\rho$  for reaction 1. That is, for the relationship  $\int_R \Delta H^\circ_f = \sigma^0\rho$  (for polar effects) the predicted values of  $\rho$  (in kcal/mole  $-\sigma^0$  units) are obtained as  $\rho = -\Delta_0/2.75$ , where  $\Delta_0 = \int_{H(c)}^{p-X_0} - \int_{H(u)}^{p-X_0}$  (values of these parameters are given in Table I of ref 5 for the acids  $\text{AlCl}(\text{C}_2\text{H}_5)_2$ ,  $\text{BF}_3$ ,  $\text{BCl}_3$ ,  $\text{AlCl}_2\text{C}_2\text{H}_5$ ,  $\text{AlCl}_3$ ,  $\text{BBR}_3$ , and  $\text{BI}_3$ ).

**Limitations of the Linear SEE Relationship.** LCAO-MO theory *does not* indicate completely general linear relationships between local charge density and electronic energy.<sup>10</sup> Consequently the SEE relationship,

(10) C. A. Coulson, *Proc. Phys. Soc. (London)*, **A65**, 933 (1952); L. Goodman and H. Shull, *J. Chem. Phys.*, **23**, 33 (1955).

which makes a specialized use of such linearity,<sup>2</sup> is anticipated to have structural limitations. These limitations are not well defined by present theory and, in any case, must be subjected to experimental determination.

The results of this and previous investigations,<sup>2,11</sup> leave little doubt that the SEE relationships are satisfactorily linear for  $p$ -fluorophenyl substitution at a fixed functional group (within the usual context of such usage). It is not necessary, however, that the energy shielding coefficient,  $m$ , be a universal constant of precisely 1.00 kcal/mole ppm.

In the formation of trityl cations from their carbinols<sup>11</sup>  $m = 0.70$  kcal/mole ppm, while in the ethane reduction to trityl anions<sup>3,12</sup>  $m = 1.30$  kcal/mole ppm. These results suggest that  $m$  increases (in magnitude) as the  $p$ -fluorophenyl label is substituted at substantially more "saturated" (less sensitive) functional centers. Unpublished results of Dr. M. G. Schwartz<sup>13</sup> and Dr. D. Gurka<sup>14</sup> with adducts of  $p$ -fluorophenol and of Mr. A. A. Grey<sup>14</sup> with adducts of  $p$ -fluorophenylboron dichloride definitely confirm this trend.

In the application of eq 4 to the present study nearly equivalent results to those listed in Table I are obtained with  $m = 1.05$  kcal/mole ppm and  $b = 0$  whereas in the application of eq 5  $m = 1.00$  or slightly smaller. However, the differences in the alternate treatments are not significant. Consequently, as a working hypothesis,  $m$  is taken to be a constant for each broadly defined functional group, (e.g., the carbonyl group in series I ketones and their Lewis acid adducts).

**Thermodynamic Considerations.** The assumed approximation  $\Delta H^\circ_f \cong \Delta E^\circ_{\text{elect}}$  more accurately must be replaced by the relationship

$$\Delta H^\circ_f = T\Delta[(H^\circ - E_0^\circ)/T] + \Delta E_0^\circ$$

where  $\Delta[(H^\circ - E_0^\circ)/T]$  represents the sum of the thermodynamic function for the products of reaction 1 minus that for the reactants, and  $\Delta E_0^\circ = \Delta E^\circ_{\text{elect}} + \Delta E^\circ_{\text{vibr}}$  where  $\Delta E^\circ_{\text{vibr}}$  is the zero point vibrational energy change for reaction 1.

Since the thermodynamic functions and  $\Delta E^\circ_{\text{vibr}}$  can be evaluated from vibrational and rotational spectroscopic data, it follows that the linear SEE relationship provides in principle a means of precise prediction of  $\Delta H^\circ_f$  from the various spectroscopic measurements and statistical thermodynamic relationships. A similar conclusion applies with respect to the *a priori* prediction of the equilibrium constant through the relationship

$$\Delta F^\circ_f = RT \ln K = T\Delta[(F^\circ - E_0^\circ)/T] + \Delta E^\circ_{\text{elect}} + \Delta E^\circ_{\text{vibr}}$$

In practice, the application of this precise relationship must await the evaluation of the precision of

(11) For shielding in substituted trityl cations cf. ref 2. Substituent shielding effects in the corresponding carbinols have been obtained: L. D. McKeever, Ph.D. Thesis, University of California, Irvine, Calif., Sept 1966. The latter shieldings parallel those obtained in the trityl cations but are only 3% as large.

(12) Cf. ref 3. The substituent shielding effects in the ethanes have been approximated as those observed in the corresponding triaryl-methanes. The latter shielding effects are approximately 7% as large as for corresponding shieldings in the trityl anions.

## Analysis of the Nuclear Magnetic Resonance Spectra of Some 2,6-Bridged Bicyclo[2.2.1]heptane Derivatives

Kermit C. Ramey,<sup>1a</sup> David C. Lini,<sup>1a</sup> Robert M. Moriarty,<sup>1b</sup> H. Gopal,<sup>1b</sup> and Harold G. Welsh<sup>1b</sup>

*Contribution from the Research and Development Department of the ARCO Chemical Company, a Division of Atlantic Richfield Company, Glenolden, Pennsylvania, and the Department of Chemistry, The Catholic University of America, Washington, D. C. Received December 15, 1966*

**Abstract:** The 60- and 100-Mc/sec nuclear magnetic resonance spectra of several bridged bicyclo[2.2.1]heptane derivatives have been analyzed in detail. These compounds possess the common structural feature of a 2,6 oxygenated bridge which may be either a lactone as in 5-*exo*-iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (1) and the 5-*exo*-bromo (2), 5-*exo*-acetoxy (3), 5-*exo*-tosyloxy (4), 2-*exo*-methyl-5-*exo*-iodo (5), 2-*exo*-methyl-5-*exo*-bromo (6) derivatives; or the 2,6 bridge may be an oxido unit as in 4-*exo*-tosyloxy-6-oxatricyclo[3.2.1.1<sup>3,4</sup>]nonane (7) and 4-*exo*-acetoxy-6-oxatricyclo[3.2.1.1<sup>3,4</sup>]nonane (8). Chemical shifts for all the protons in these structures have been assigned, and the geminal and vicinal couplings measured. Aromatic solvent shifts observed for compounds 1, 5, and 7 are discussed in terms of solvent-solute collisional complexes of defined stereochemistry. Long-range couplings for the proton pairs: 1-4, 3-*endo*-7(a), 5-*endo*-7(b), 2-*exo*-6-*exo*, 1-3-*exo*, 2-*exo*-4, and 6-*exo*-4 in compound 1 were observed and most of these were confirmed using spin-decoupling techniques. For the C<sub>2</sub>-*endo* proton doublet in the lactone derivatives it is noteworthy that the principal coupling is with the C<sub>7(b)</sub> proton; this amounts to about 2.5 cps while the C<sub>2</sub>-*endo*-C<sub>6</sub>-*exo* vicinal coupling is negligibly small (0.3 cps) and the C<sub>6</sub>-*endo*-C<sub>4</sub>-vicinal ranges from 0.5 to 1.0 cps. The nmr spectra of the 5-keto and 7-keto derivatives in the 2,6 lactone series are discussed in relationship to the changes in chemical shifts relative to the precursor secondary alcohols. The alcohol-ketone pairs are 5-*exo*,6-*endo*-dihydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (9) and 5-keto,6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (10); 6-*endo*,7(b)-dihydroxybicyclo[2.2.1]heptane-2-*endo* carboxylic acid lactone (11) and 7-keto,6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (12).

The norbornyl system has served as a substrate for the generation and evaluation of numerous mechanistic hypotheses in modern organic chemistry. Mechanistic conclusions originating from studies in the norbornyl series frequently have been based upon the structures of rearranged products. Detailed nuclear magnetic resonance spectral analyses in this series obviously are of importance in facilitating the elucidation of rearrangement products. Moreover, due to the conformational rigidity of these systems, long-range

couplings which are often of an unexpectedly large magnitude may be detected. This paper presents detailed analyses of the spectra of compounds 1-8. The compounds included in this study are of current and particular interest because of uncertainties of interpretation<sup>2a</sup> and previous erroneous assignments.<sup>2b</sup>

### Chemical Shifts

In a preliminary communication of a portion of this work,<sup>3</sup> we pointed out that the chemical shifts of the C<sub>1</sub>- and C<sub>2</sub>-*exo* protons in compound 1 were anomalous in the sense that the C<sub>1</sub> proton appeared at a lower field position relative to the C<sub>2</sub>-*exo* proton which is attached to the carbon atom bearing the carbonyl group of the lactone. This assignment was required to explain the magnitude of the couplings associated with the C<sub>6</sub>-*exo* proton. An earlier interpretation of the spectrum of 2 used the reverse assignment of the chemical shift of the C<sub>1</sub>- and C<sub>2</sub>-*exo* protons.<sup>2b</sup> This incorrect assignment was used recently by Jensen and Miller<sup>2a</sup> who corrected stereochemical assignments of Traylor and Factor for the structure of the oxymercuration product derived from 5-norbornene-2-*endo*-car-

boxylic acid.<sup>4a,b</sup> The incorrect chemical shift assignments used by Jensen and Miller for the  $\text{C}_1$ - and  $\text{C}_2$ -*exo* protons, however, do not influence the validity of their conclusions with respect to the configuration of the  $\text{C}_6$ -*endo* proton in compounds 1 and 2 which they studied.

Figure 1A–C presents the 100-Mc/sec nmr spectra of compounds 2, 6, and 8, respectively (Table I presents chemical shifts). For lactones 2 and 6 one may immediately discern a similarity; namely, three resonances equivalent to one proton each appear at downfield positions and these resonances are clearly

(4) (a) T. G. Traylor and A. Factor, Abstracts, 147th National Meeting of the American Chemical Society, Philadelphia, Pa., April 1964, p 36N. (b) Professor Traylor informed us of his revision of the stereochemistry originally proposed by him and Factor<sup>4a</sup> for the oxymercuration product of 5-norbornene-2-*endo*-carboxylic acid on Nov 20, 1964, in a seminar in this department.

separated from the complex upfield absorption. The absorptions around  $\tau$  5.1 and 6.1 are logically assigned to the  $\text{C}_6$ -*exo* and  $\text{C}_5$ -*endo* protons, respectively. The resonance at  $\tau$  6.75 in 2 might be due to the  $\text{C}_2$ -*exo* proton but this assignment leads to a number of unreasonable interactions. For example, spin-decoupling experiments revealed that the proton in 2 at  $\tau$  6.75 was coupled with the  $\text{C}_6$ -*exo* proton to the extent of 5 cps. This would be an unprecedentedly large long-range coupling for such protons. This coupling was clearly better accommodated by a vicinal rather than a 1,3 arrangement of these interacting protons. The spectrum of 6 clarifies this point in that a methyl group occupies the site in this derivative of the  $\text{C}_2$ -*exo* proton present in 1 and 2, yet a resonance still occurs at  $\tau$  7.20. Accepting this alternative assignment, *i.e.*, that  $\text{C}_1$  proton gives rise to the absorption at  $\tau$  7.2, appearance of this proton in 6 as principally a doublet is due to the absence of a proton at  $\text{C}_2$  for coupling. Furthermore, any reasonable analysis of spectra in this series, as will be shown below, demands these relative assignments of the  $\text{C}_1$ - and  $\text{C}_2$ -*exo* protons.

The reason for this unexpected reversal in the chemical shifts of the  $\text{C}_1$ - and  $\text{C}_2$ -*exo* protons is based upon a model in which the  $\text{C}_1$  proton is axial with respect to the lactone ring and is located in the region of maximum deshielding resulting from the ring current associated with the lactone carbonyl group. This interpretation is also consistent with the results obtained for compounds 5 and 6. The upfield shifts of about 0.4 ppm for the  $\text{C}_1$  proton in compounds 5 and 6 is probably due to the anisotropy of the carbon-carbon  $\sigma$  bond of the methyl group at  $\text{C}_2$ .<sup>5</sup> Accordingly, the  $\text{C}_3$ -*exo* proton in 1 should also experience extra shielding, and reference to the data in Table I bears out this prediction. The difference in magnitude of the upfield shift is associated with the dihedral angle between the  $\text{C}_2$ - $\text{CH}_3$  bond and the  $\text{C}_1$ -H,  $\text{C}_3$ -*exo*-H, and  $\text{C}_3$ -*endo*-H bonds. The maximum upfield shift is experienced by the  $\text{C}_3$ -*exo* proton,  $\Delta\delta \text{C}_3\text{-exo}(1)\text{-C}_3\text{-exo}(5) = +0.54$ . The dihedral angle here is close to  $0^\circ$ . The  $\text{C}_2$ - $\text{CH}_3$  and  $\text{C}_1$ -H dihedral angle is about  $40^\circ$  and  $\Delta\delta \text{C}_1(1)\text{-C}_1(5) = +0.44$ . The dihedral angle for the  $\text{C}_2$ - $\text{CH}_3$ - $\text{C}_3$ -*endo*-H is about  $120^\circ$  and  $\Delta\delta \text{C}_3\text{-endo}(1)\text{-C}_3\text{-endo}(5) = -0.42$ . Thus, this proton suffers a large deshielding effect due to the anisotropy of the C- $\text{CH}_3$  bond. The effect upon the  $\text{C}_6$ -*exo* and  $\text{C}_7$ (b) protons is very small. Replacement of the carbonyl group of the lactone by a methylene group, as in compounds 7 and 8, causes a further upfield shift of the  $\text{C}_1$  protons relative to the position in the lactones.

The spectrum of 8, Figure 1C, exhibits a typical AB part of an ABX pattern for protons 8(a) and 8(b). Inspection of models reveals that only one of the  $\text{C}_8$  methylene protons has the correct geometry for spin-spin coupling with the  $\text{C}_2$ -*exo* proton.

In most cases the assignment of resonances corresponding to the  $\text{C}_3$ -*exo*,  $\text{C}_3$ -*endo*, and 7(a), 7(b) proton pairs was straightforward. The expected larger value of  $J_{3\text{-exo-3-endo}}$  over  $J_{7(a)-7(b)}$  as found by Laszlo and Schleyer was of diagnostic value here.<sup>6</sup> Differentiation of the chemical shifts of the individual protons of these

	7.20	5.15	6.21	7.41	8.41	8.19	8.84 (CH <sub>3</sub> )	7.71	8.24
	7.48	5.95	5.91	7.76	8.21	9.10	7.76	8.15	8.53
	7.38	5.94	5.68	7.78	8.17	8.90	7.70	8.10	8.48

Chemical shifts for the protons in the 8 positions are  $\tau$  6.53, and 6.47 for compound 7 and 6.19 and 6.34 for compound 8. <sup>b</sup> Note numbering of the oxido methylene group as C<sub>4</sub> is not correct as far as nomenclature is concerned; *i.e.*, compounds 7 and 8 are tri-1<sup>3</sup>,<sup>4</sup>nonane derivatives. However, we use the above incorrect nomenclature in order to focus on the relationship of these compounds with their norbornyl analogs.

Assignments was accomplished by analysis of stereochemical long-range coupling using decoupling techniques *vide infra*. The assignments of the C<sub>2</sub>-*exo*, and C<sub>4</sub> protons were implied from previous work which showed that the spin-spin coupling of the end C<sub>2</sub>-*exo* protons should be relatively large, 11.5 cps, while the coupling of the C<sub>4</sub> proton C<sub>2</sub>-*exo*, C<sub>3</sub>-*endo*, C<sub>5</sub>-*endo*, C<sub>7</sub>(a), and C<sub>7</sub>(b) should be comparatively smaller.<sup>7a,b</sup> Confirmation of the above chemical shift assignments derive from the nmr spectra of compounds 9 and 12.

In the case of alcohol 9 the C<sub>5</sub>-*endo* proton at 6.0 appears as a singlet peak at  $\tau$  6.30. The peak half-height is 2.8 cps. The C<sub>6</sub>-*exo* proton appears as a doublet at  $\tau$  5.5. The principal coupling of the C<sub>6</sub>-*endo* proton is with the C<sub>7</sub>(b) proton, while the coupling, 5.0 cps, for the C<sub>6</sub>-*exo* proton is with the C<sub>1</sub> proton. Oxidation of 9 to 10 removes the C<sub>1</sub> proton absorption. The C<sub>6</sub>-*exo* proton is shifted by +0.55 ppm. Similarly, for 11, the C<sub>7</sub>(b) proton appears as a singlet with peak width at a half-height of 4 cps. The C<sub>1</sub> proton appears as a doublet with further small splitting ( $J_{6-exo-1} \sim 5$  cps,  $J_{7(b)-1} \sim 1.5$  cps,  $J_{1-4} \sim 1$  cps). Oxidation of 11 to 12 removes the C<sub>7</sub>(b) resonance and the C<sub>1</sub> resonance is essentially unshifted. The small upfield splitting also vanishes as expected.

L. Williamson, *J. Am. Chem. Soc.*, **85**, 516 (1963). (b) These assignments agree with theoretically derived ones: J. Karplus, *J. Chem. Phys.*, **31**, 1 (1959).

Further points of interest with respect to chemical shifts as presented in Table I are (a) the C<sub>7</sub>(b) proton resonates at higher field than its C<sub>7</sub>(a) counterpart; (b) the C<sub>3</sub>-*endo* proton occurs at higher field position than the C<sub>3</sub>-*exo* except in the case of the C<sub>2</sub> methyl derivatives. Again this may be explained in terms of the anisotropy of the carbon-carbon  $\sigma$  bond of the methyl group; (c) reasonable consistency prevails for the relative chemical shifts of structurally related protons. Finally, since these assigned chemical shifts are largely based on spin-spin decoupling this aspect of the work will be discussed next.

**Spin-Spin Decoupling.** Figures 2 and 3 show expanded sweeps at 100 Mc/sec of the upfield and downfield portions of the spectrum of compound 2 in benzene solution. Relative to the spectrum of this compound shown in Figure 1, a considerable simplification of the overlapping resonances is immediately apparent. Advantage was taken of this solvent-induced separation of proton chemical shifts, and spin-decoupling experiments were performed using benzene solutions.

Based upon the discussion presented above, the chemical shifts of the C<sub>5</sub>-*endo* and C<sub>6</sub>-*exo* protons can be assigned with strong certainty. These two resonances were used as probes for assigning other protons in the more complicated high-field portion of the spectrum. While the chemical shift of the C<sub>1</sub> proton also appeared secure on the basis of arguments presented above, we nonetheless attempted an analysis based upon the assignments of Crundwell and Templeton;<sup>2b</sup> *i.e.*, the three downfield resonances would correspond to protons C<sub>6</sub>-*exo*, C<sub>5</sub>-*endo*, and C<sub>2</sub>-*exo* with increasing field strength, respectively. This set of assignments together with the assignments of protons C<sub>1</sub> and C<sub>4</sub> to the resonances at  $\tau$  7.35 and 7.48 for 2 used in conjunction with the other assignments as listed in Table I yielded a number of unreasonable interactions such as  $J_{4-3-exo} = 10.5$  cps,  $J_{2-exo-4}$  and  $J_{2-exo-6-exo} \cong 5$  cps. These results, which indicate that the three downfield resonances are correctly assigned (Table I), were used with spin decoupling to assign the upfield components of the spectra.

The expanded spectrum of the C<sub>6</sub>-*exo* and C<sub>5</sub>-*endo* protons of 2 is shown in Figure 4. Part a depicts the normal C<sub>6</sub>-*exo* proton with coupling constants of 5

Figure 2. Downfield portion of the NMR spectrum of compound 2 in solution in  $C_6H_6$ .

Figure 3. Upfield portion of the NMR spectrum of compound 2 in solution in  $C_6H_6$ .

and 1 cps. Part b shows the  $C_5$ -*exo* proton absorption upon irradiation of the  $C_1$  proton at  $\tau$  7.29. Thus, the 5-cps coupling between the  $C_1$ - and  $C_5$ -*exo* proton is established clearly. Irradiation of the  $C_2$ -*exo* proton at 7.83 cps (part c) eliminates the long-range 1.0-cps  $J_{4-exo-2-exo}$  as well as  $J_{4-exo-4}$ . Irradiation of the  $C_5$ -*endo* proton at  $\tau$  6.43 does not alter the resonance of the  $C_5$ -*exo* proton. Hence  $J_{5-exo-5-endo}$  is less than 0.3 cps. Turning to the  $C_5$ -*endo*, Figure 4, part d, shows the unperturbed resonance of the  $C_5$ -*endo* proton; it exhibits a 2.4- and a 0.5-cps coupling. Surprisingly irradiation of the  $C_4$  proton (part b) did not remove the 2.4-cps, but rather only the 0.5-cps coupling. Assuming a zigzag geometric requirement for long-range coupling over four bonds, only the  $C_1$  and  $C_{7(b)}$  protons bear such a relationship to the  $C_5$ -*endo* proton.

Irradiation at  $\tau$  8.69 removes the 2.4-cps coupling, as shown in part e of Figure 4. Since the chemical shift of the  $C_1$  proton is known, and the resonance in the  $\tau$  8.7 region possesses the appearance of a member of an AB pattern, the  $C_{7(b)}$  proton is fixed. Furthermore, the chemical shift of the  $C_{7(a)}$  proton is revealed as the other part of the  $C_7$  AB pattern. In Figure 5, are shown typical decoupled spectra obtained using the frequency sweep technique. Part A shows the upfield part of the normal spectrum of 2 in benzene solution; part B shows the spectrum obtained upon irradiation of

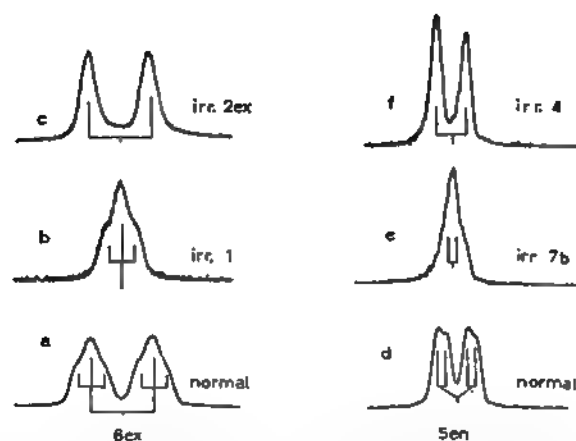

Figure 4. Expanded sweep of  $C_5$ -*exo* resonance of compound 2: a, normal; b, decoupled from proton 1; c, decoupled from proton 2-*exo*; and d, normal resonance of  $C_5$ -*endo* of compound 2; e, decoupled from proton 7(b); and f, decoupled from proton 4.

the  $C_4$  proton at  $\tau$  7.65. First to be noted in going from left to right is the beat note at  $\tau$  7.65 which is recorded at reduced amplitude. This indicates the position of irradiation. It is followed by a distorted region extending about 30 cps in both directions from the point of irradiation. Secondly, the appearance of the 7(a) resonance, particularly the upfield part, confirms the interaction  $J_{1(a)-4} = 1.4$  cps. Next and more clearly, despite the beat note in the region,  $J_{2-exo-4} = 3.8$  cps is confirmed. Lastly, in the upfield region both  $J_{2-endo-4} = 0.8$  cps and  $J_{7(b)-4} = 1.5$  cps are confirmed. Part C shows the spectrum resulting from irradiation of the  $C_1$  proton at  $\tau$  7.3. The overlap of the beat note and the resonance of the  $C_4$  complicates the interpretation, but nevertheless protons  $C_1$  and  $C_2$  obviously interact. The resonance of the  $C_2$ -*exo* proton confirms the 4.9-cps interaction with the  $C_1$  proton, and also a 1.4-cps coupling of proton  $C_1$  with proton  $C_{7(a)}$ .

The spectra shown in Figure 5 are meant to be representative. In order to confirm the various interactions indicated, the individual resonance under study was expanded to 50 cps and decoupled.

geminal and vicinal coupling constants for the series of compounds are collected in Tables II and III, respectively. The omissions in Table III correspond to those in which accurate values could not be obtained because of unresolvable overlap.

**Long-Range Couplings.** Long-range interactions of appreciable magnitude across four saturated bonds have been observed for a number of bicycloheptane<sup>8,9</sup> and bicyclohexane<sup>10,11</sup> derivatives. These long-range interactions appear to depend primarily upon the spatial arrangements of the interacting protons, although other factors such as electronegativity and steric effects of substituents appear also to be of importance. Recent studies have shown, both theoretically and experimentally, that a near-planar zigzag arrangement of the interacting protons is necessary for detectable interactions. With currently available techniques this amounts to about 0.3 Å. On this basis, for the structure below, proton pairs, 1-3-*exo*, 2-*exo*-4, 6-*exo*-4, 5-*endo*-7(b), 3-*endo*-7(a), 2-*exo*-6-*exo* are expected to exhibit long-range interactions. For similar systems, couplings of 3-4 cps<sup>8</sup>

have been reported between protons of the  $C_3$ -*endo*-7(a), and  $C_5$ -*endo*-7(b) type, 0.7-1.8 cps for protons of the  $C_2$ -*exo*- $C_6$ -*exo* variety,<sup>12</sup> and 0.8-1.4 cps for protons of the 1-4 type.<sup>12</sup> A weak coupling between protons  $C_3$ -*exo*- $C_1$  and  $C_5$ -*exo*- $C_4$  has been postulated,<sup>13</sup> but no values were reported.

In the present work values of  $J_{7(a)-3-endo}$  and  $J_{7(b)-5-endo}$  ranging from 1.3 to 3.2 and 1.7 to 2.6 cps, respectively, were observed. These results are similar to those reported by Musher,<sup>9</sup> but smaller than the values found by Meinwald and Meinwald<sup>8</sup> for related compounds. The published data<sup>8,9</sup> seem to indicate that there is a fairly large substituent effect upon these interactions particularly for compounds of the type 1-4. However, in the system under investigation in this study, the substitution of a methyl group in the  $C_2$ -*exo* position (5-6) appears to increase  $J_{7(a)-3-endo}$  while decreasing  $J_{7(b)-5-endo}$ . Furthermore, a change in the oxygenated bridge spanning the 2-6 positions produces a smaller value of  $J_{7(b)-5-endo}$  than that of  $J_{7(a)-3-endo}$ . This seems to indicate that the long-range couplings are sensitive to changes in the planarity of the zigzag arrangement of the interacting atoms. The relatively small values of  $J_{1-4}$  and  $J_{2-exo-6-exo}$  for which the interacting protons conform to a more strictly planar arrangement than other cases, as

judged by inspection of scale models, indicate that planarity of the systems may not be the dominant factor in determining the magnitude of coupling over four bonds. Furthermore, a direct relationship does not appear to exist between the size of the coupling constant and the 1,3 proton internuclear distance. Thus, inspection of scale models reveals that the  $C_1$ - $C_3$ -*exo* proton distance in 2 is 4 Å while the  $C_5$ -*endo*- $C_7(b)$  and  $C_2$ -*exo*- $C_6$ -*exo* distances are 4.4 Å. Yet, the latter gives rise to considerably larger long-range couplings.

As shown in Table IV, a number of small long-range couplings were observed involving  $C_6$ -*exo*-4,  $C_1$ -3-*exo*, and  $C_2$ -*exo*-4 for compounds 1-8. These interactions were usually less than 1 cps and were generally difficult to detect in normal spectra. Under the condition of our decoupling experiments at 60 and 100 Mc/sec, it was possible to detect long-range couplings as small as 0.5 cps.

## Solvent Effects

The effect of solvent upon proton chemical shifts is well documented.<sup>14,15</sup> Solvent-solute interactions be-

Structural information from these studies derives from the formation of a weakly associated solvent-solute collisional complex of definite stereochemical composition.<sup>18</sup> A consequence of the nonrandom orientation of the aromatic ring with respect to the polar solute is that nuclei near the disk-like ring are shielded relative to nuclei either remote from the aromatic ring or coplanar with it. The structure of the collisional complex is governed by a weak polar attrac-

tion of the aromatic ring for the partially positively charged amide or lactam nitrogen. A comparable interaction is conceivable for *cis* lactones of the type under study.

Connolly and McCrindle<sup>19</sup> have studied benzene-induced chemical shifts for a series of lactones. Table V lists dilution shifts for compounds 1, 5, and 7. The shifts observed for the two lactones 1 and 5 are large, while those for the oxido compound 7 are small. Based upon the model for the benzene-lactone complex proposed above, one might predict that the  $\text{C}_1$  proton would experience the largest upfield shift and the  $\text{C}_2$ -*exo* proton should experience a relatively smaller upfield shift. These predictions are realized and they may be further rationalized on the basis of the tendency of the benzene molecule to avoid the partially negatively charged carbonyl oxygen atom and residue closer to  $\text{C}_1$ . On the average, the  $\text{C}_1$  proton is the more highly shielded. Also, in the assumed model, the benzene ring and the front face of the molecule, which contains the lactone ring, lie in parallel planes. The  $\text{C}_1$  proton, therefore, is axial and lies closer to the shield portion of the aromatic. This last point offers additional proof for the correctness of the  $\text{C}_1$  proton assignment. The simplified cation of the spectrum observed in benzene solution for compound 2 (Figure 6) relative to the *d*-chloroform solution enables a more definitive analysis of the  $\text{C}_3$ -*endo*- $\text{C}_7$ (b),  $\text{C}_3$ -*exo*- $\text{C}_7$ (a), and  $\text{C}_2$ -*exo*- $\text{C}_4$  protons. Finally, note should be made of the advantage of combining spin-spin decoupling with dilution shifts observed for solutions of polar solutes such as *cis* lactones with aromatic solvents such as benzene.

## Experimental Section

The spectra were obtained using Varian HA-100 and A-60 spectrometers. Samples were run as 10% (w/v) solutions in  $\text{CDCl}_3$  and  $\text{C}_6\text{H}_6$  with tetramethylsilane as an internal reference. Decoupling was carried out with the HA-100 spectrometer utilizing the frequency sweep technique and the V-6058-1 spin decoupler at 60 Mc/sec, which utilizes the field-sweep technique. A Hewlett-Packard audiofrequency oscillator 201C in conjunction with a Hewlett-Packard audiofrequency counter 5512A was used for frequency sweep decoupling and for the calibration of both instruments.

**5-*exo*-Iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (1)** was prepared according to the method of Ver Nooy, *et al.*,<sup>20</sup> and had mp 59–60° (lit.<sup>20</sup> 58–59°),  $\nu_{\text{C=O}}$  1783  $\text{cm}^{-1}$ .

**5-*exo*-Tosyloxy-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic Acid Lactone (4).** To a solution of 1.2 g of alcohol 9 dissolved in the minimum amount of dry pyridine, 2.0 g of *p*-toluenesulfonyl chloride was added. The mixture was warmed on steam bath until solution was complete, and then the reaction mixture was allowed to stand at room temperature overnight. Ice water was added, and the mixture was extracted thoroughly with ether. The ether solution was washed with water, a dilute solution of hydrochloric acid, and then with a saturated solution of sodium bicarbonate. The solution was dried with magnesium sulfate and then concentrated to dryness *in vacuo*. The residue was recrystallized from ether-pentane to yield 2.07 g (87.5%), mp 84–95°. *Anal.* Calcd for C<sub>15</sub>H<sub>18</sub>O<sub>6</sub>S: C, 58.58; H, 5.21; S, 36.21. Found: C, 58.72; H, 5.21.

**5-*exo*,6-*endo*-Dihydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (9)** was prepared according to the method of Henbest and Nichols and had mp 155–157° (lit.<sup>22</sup> 160°).

**5-Keto-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (10).** A solution of 400 mg of ruthenium dioxide in carbon tetrachloride was prepared according to the procedure of Ito.<sup>23</sup> This solution was added dropwise to a suspension in carbon tetrachloride of 5-*exo*,6-*endo*-dihydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (9), 5 g, 0.033 mole, with stirring and cooling. Then, 7.0 g (0.033 mole) of sodium metaperiodate solution was added dropwise over a 1-hr period. The reaction mixture was stirred at ice temperature for 4 hr, then at room temperature for 18 hr. The excess oxidizing agent was removed by addition of isopropyl alcohol. The layers were separated and the aqueous layer was thoroughly extracted with chloroform. The chloroform and carbon tetrachloride solutions combined, dried over magnesium sulfate, and concentrated to dryness *in vacuo*. The resulting thick oil, 1.5 g, was sublimed at 75° (0.5 mm). The resulting sublimate, 1.2 g, showed five spots on tlc. The sublimate was chromatographed upon silica using a column (35 × 3.5 cm) of 100 g of silica gel prepared with benzene. The column was first eluted with benzene-chloroform (1:1), then with chloroform, and finally with chloroform-methanol (97:3). The first eight fractions were oils and were put aside. Fraction 9 gave five spots in thin layer chromatography and infrared spectrum showed a strong carbonyl absorption at 1790 cm<sup>-1</sup>, doublet with a weak absorption band at 1705 cm<sup>-1</sup>. Fractions 10–14, the eluates of chloroform, showed mainly one spot in thin layer chromatography and the infrared spectrum of each showed strong carbonyl absorption at 1800, 1770 cm<sup>-1</sup>, doublet, and a weak absorption band at 1705 cm<sup>-1</sup>. Fractions 15–17, eluates of chloroform-methanol (97:3), showed strong carbonyl absorption at 1705 cm<sup>-1</sup> and relatively weak absorption in the above-mentioned region. Fractions 18 and 19, chloroform-methanol (97:3), were identified as unreacted starting material by infrared comparison of authentic sample.

Fraction 11 (100 mg) deposited some crystalline material on keeping in chloroform solution for a few days. Filtration of crystals from the solution with ether afforded 30 mg of compound. Recrystallization with chloroform gave quite pure crystalline sample, mp 196°, showing strong carbonyl absorption in the infrared at 1770 cm<sup>-1</sup>, doublet with no hydroxyl absorption band. This showed a single spot in thin layer chromatogram using a chloroform-methanol (97:3) system as given before. The molecular weight of 152 was confirmed by a high-resolution mass spectrum. **5-*exo*-Iodo-6-*endo*,2-*exo*-methylbicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (5)** was prepared according to the method of Meek and Trapp<sup>24</sup> and had mp 85–86° (lit.<sup>24</sup> 83–86°),  $\nu_{C=O}$  1780

**5-*exo*-Bromo-6-*endo*,2-*exo*-methylbicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (6)** was prepared according to the method of Meek and Trapp<sup>24</sup> and had mp 74–75° (lit.<sup>24</sup> 74–75°),  $\nu_{C=O}$  1790 cm<sup>-1</sup>.

**4-*exo*-Tosyloxy-6-oxatricyclo[3.2.1.1<sup>3,5</sup>]nonane (7).** A solution of 4.5 g of 4-*exo*-hydroxy-6-oxatricyclo[3.2.1.1<sup>3,5</sup>]nonane and 9 g of *p*-toluenesulfonyl chloride in 12 ml of very dry pyridine was stored overnight at room temperature. After processing the reaction mixture in the usual way, the crude product was recrystallized from ether-pentane giving 7.6 g (77%), mp 86–87°. *Anal.* Calcd for C<sub>15</sub>H<sub>18</sub>O<sub>4</sub>S: C, 61.20; H, 6.16. Found: C, 61.50; H, 6.27.

**4-*exo*-Acetoxy-6-oxatricyclo[3.2.1.1<sup>3,5</sup>]nonane (8)** was prepared according to the method of Henbest and Nichols<sup>22</sup> and had mp 52–53° (lit.<sup>22</sup> 50–52°).

**7(a),6-*endo*-Dihydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone (11).** A three-necked, 300-ml, round-bottomed flask was equipped with an efficient stirrer and a condenser to which was attached a calcium chloride drying tube. Dried lead tetraacetate (20 g, 0.044 mole), dry CaCO<sub>3</sub> (12 g), and 200 ml of dry benzene were introduced into the flask, and the mixture was stirred at reflux for approximately 30 min. *exo*-Bicyclo[2.2.1]hept-5-ene-2-carboxylic acid<sup>25</sup> (3 g, 0.022 mole) was then added after which refluxing was maintained for an additional 48 hr.

The solution was allowed to cool to room temperature and was then filtered through Celite. The filtrate was diluted with ether, washed with a small amount of saturated aqueous NaHCO<sub>3</sub>, dried over MgSO<sub>4</sub>, and concentrated *in vacuo*. Chromatography of the resulting yellow oil (2.5 g) on 100 g of silica gel (Baker) [elution with ether-benzene (1:4)] afforded 1.5 g (35%) of 7(a)-acetoxy-6-*endo*-hydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone. Two recrystallizations from acetone-pentane gave an analytical sample, mp 113–114°,  $\nu_{C=O}$  1735 and 1775 cm<sup>-1</sup>. *Anal.* Calcd for C<sub>10</sub>H<sub>12</sub>O<sub>4</sub>: C, 61.21; H, 6.17. Found: C, 61.07; H, 6.17.

The acetoxy lactone (2.09 g) and 4.5 g of potassium carbonate were refluxed in a mixture of 40 ml of water and 60 ml of methanol for 4 hr. At the end of this time, the water and methanol were removed using a rotary evaporator. The residue was dissolved in 30 ml of water and extracted twice with ethyl acetate to remove any of the unreacted acetate. The aqueous layer was acidified by dropwise addition of 50% H<sub>2</sub>SO<sub>4</sub>, after which the solution was continuously extracted with ethyl acetate for 36 hr.

The ethyl acetate solution was washed with three portions of saturated aqueous NaHCO<sub>3</sub> solution, dried over MgSO<sub>4</sub>, and concentrated to yield 0.914 g of crude 7(a),6-*endo*-dihydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone. Continuous extraction of the NaHCO<sub>3</sub> combined washings for 24 hr afforded an additional 0.30 g of crude product, total yield 74%. Two recrystallizations from acetone-ligroin gave an analytical sample, mp 203–204°,  $\nu_{O-H}$  3600 and 3440 cm<sup>-1</sup>;  $\nu_{C=O}$  1775 cm<sup>-1</sup>. *Anal.* Calcd for C<sub>8</sub>H<sub>10</sub>O<sub>4</sub>: C, 62.32; H, 6.54. Found: C, 62.13; H, 6.60.

**7-Keto-6-*endo*-hydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone (12).** A solution of 2.4 g of 7(a),6-*endo*-dihydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone in 8.2 ml of water was maintained at 20° for a period of 45 min while 7.4 ml of 6 *N* chromic acid was added dropwise with stirring. After an additional 10 hr of stirring, 0.3 ml of 2-propanol was introduced to decompose any excess chromic acid and the solution was extracted several times with ethyl acetate. The combined extracts were dried over magnesium sulfate and concentrated at room temperature on a rotary evaporator. Elution chromatography of the crude product mixture (2.4 g) on 140 g of silica gel (Baker) with ether-benzene (1:4) afforded initially 0.67 g (27%) of crude 7-keto-6-*endo*-hydroxybicyclo[2.2.1]-2-*endo*-carboxylic acid lactone followed immediately by approximately 0.5 g of unreacted starting alcohol. A pure

## New Heteroaromatic Compounds. XXV.<sup>1</sup> Studies of Salt Formation in Boron Oxyacids by <sup>11</sup>B Nuclear Magnetic Resonance

Michael J. S. Dewar and Richard Jones<sup>2</sup>

Contribution from the Department of Chemistry, The University of Texas,  
Austin, Texas 78712. Received December 22, 1966

**Abstract:** The <sup>11</sup>B nmr spectra of several compounds containing the group BOH have been measured in neutral and alkaline solution. Salt formation shifts the <sup>11</sup>B resonance far upfield (> 13 ppm) in the case of boric acid and simple arylboronic acids, the line width remaining unchanged or becoming narrower; this indicates that such compounds behave as Lewis acids toward base. The B–OH derivatives of several borazaro<sup>3</sup> compounds are quite different in this respect, salt formation leading to small downfield shifts (3–7 ppm) in the <sup>11</sup>B resonance, and also to extreme broadening of the lines. Here salt formation must involve proton transfer, in agreement with earlier conclusions<sup>3</sup> and implying that compounds of this type are indeed aromatic.

Trivalent boron compounds are well known to behave as Lewis acids, combining with base to form coordination compounds (e.g.,  $\text{H}_3\text{N} \rightarrow \text{BF}_3$ ); an ambiguity therefore exists in the case of compounds which contain the grouping BOH and so could act either as protic acids, or as Lewis acids, toward base. Thus hydroxide ion could either deprotonate such a compound to give a planar ion,  $\text{R}_2\text{BO}^-$  (eq 1), or it could add to boron to form an ion in which boron is now quadricovalent and tetrahedral (eq 2).

The Raman spectrum of boric acid in alkali indicates that it behaves as a Lewis acid,<sup>4</sup> forming the ion  $\text{B}(\text{OH})_4^-$ , and the available evidence, while scanty, seems to suggest<sup>5</sup> that arylboronic acids act likewise. On the other hand, B–OH derivatives of borazaro compounds<sup>3</sup> seem to behave as protic acids, judging by comparisons of their ultraviolet spectra in neutral and alkaline solu-

tion; this difference has been attributed to the aromaticity of the boron-containing rings in compounds of this kind, the boron being consequently reluctant to adopt a tetrahedral geometry.

It seemed to us that <sup>11</sup>B nmr spectroscopy could provide a definite distinction between the two possible modes of salt formation. Conversion of trivalent planar boron to quadricovalent tetrahedral boron would be expected<sup>6</sup> to produce a large upfield shift in the <sup>11</sup>B resonance, due to the greater shielding of boron in compounds where four pairs of valence electrons surround the boron atom; the available evidence supports this conclusion. Thus the <sup>11</sup>B chemical shifts (relative to trimethyl borate) of quadricovalent boron compounds almost all lie above 7 ppm, while compounds with lower chemical shifts contain planar trivalent boron.<sup>7</sup> Salt formation according to eq 2 should therefore lead to a large upfield shift of the <sup>11</sup>B resonance, while salt formation according to eq 1 should produce a much smaller change.

Conversion of boric acid to borate ion is indeed accompanied<sup>7</sup> by a large upfield shift (17.5 ppm) in the <sup>11</sup>B resonance, as would be expected if the ion has the tetra-

hedral structure  $\text{B}(\text{OH})_4^-$ . However this observation cannot in itself be taken as evidence for such a structure since one cannot estimate *a priori* what the chemical shift would be for a planar ion such as  $(\text{HO})_2\text{BO}^-$ . In other words, one needs for comparison a reference compound  $\text{R}_3\text{BOH}$  in which salt formation involves loss of a proton (eq 1) rather than addition to boron (eq 2). Now independent evidence had suggested<sup>3</sup> that this is the case for B-OH derivatives of several borazaro compounds, in particular 10-hydroxy-10,9-borazarophenanthrene (I), 2-hydroxy-2,1-borazonaphthalene (II), and 4-hydroxy-4,3-borazaroisoquinoline (III). It seemed to us that by comparing the

$^{11}\text{B}$  nmr spectra of such compounds in neutral and alkaline solution with corresponding spectra for conventional boron oxyacids, we might kill two birds with one stone. Not only might the comparison provide a definite and general criterion between the two modes of salt formation, but it could also provide unambiguous evidence that compounds such as I-III do indeed act as protic acids. This is an important point, since the reluctance of boron to undergo addition provides one of the strongest lines of evidence that compounds of this type are indeed aromatic.<sup>3</sup>

We have, therefore, measured the  $^{11}\text{B}$  nmr spectra of I-III in neutral and alkaline solution, and also the corre-

sponding spectra of boric acid (IV), phenylboronic acid (V), o-tolylboronic acid (VI), boraphthalide (VII), and 4-hydroxy-4,3-boroxaroisoquinoline (VIII). For comparison, we also measured the spectrum of 4-methyl-4,3-borazaroisoquinoline (IX) and that of trimethyl borate in methanol and in methanolic sodium methoxide; in the latter case salt formation can take place only by addition to boron, giving the tetrahedral ion  $\text{B}(\text{OMe})_4^-$ .

## Results

The nmr spectra were measured with a Varian DP-60 spectrometer, using trimethyl borate, or the diethyl ether-boron trifluoride complex, as external standards. The results are listed in Table I. The chemical shifts are believed to be accurate to  $\pm 0.5$  ppm. The various compounds were prepared by the methods described in the references quoted and their physical properties agreed with those previously reported. The chemical

shifts for trimethyl borate and the tetramethoxyboride ion,  $\text{B}(\text{OCH}_3)_4^-$ , are in good agreement with values reported by Phillips, *et al.*<sup>8</sup>

## Discussion

It is immediately obvious that the compounds listed in Table I fall into two distinct categories. One group shows a large upfield shift ( $>13$  ppm) on passing from neutral to alkaline solution, comparable with the difference between trimethyl borate and the ion  $\text{B}(\text{OCH}_3)_4^-$ , while the other group shows a small downfield shift (3–7 ppm). The arguments given above seem to suggest unequivocally that compounds of the first group are acting as Lewis acids, those of the second group as protic acids.

This conclusion is further supported by the changes in line width accompanying salt formation. Resonances due to  $^{11}\text{B}$  are usually broad, due to quadrupole relaxation; two factors can influence the relative importance of this in a boron oxyacid and in its conjugate base. In the first place, there is a contribution due to unsymmetrical field gradients about boron inside the molecule or ion; these should be less important in an ion formed by addition to boron than in one formed by loss of a proton, since the electron distribution about a quadrivalent tetrahedral boron atom must, in general, be more symmetrical than that about a planar trivalent one. An effect of this kind is well known in the case of nitrogen,  $^{14}\text{N}$  nmr lines being much sharper for ammonium ions than for the corresponding amines.<sup>9</sup> A second source of quadrupole relaxation is provided by fluctuating electric potentials due to surrounding molecules; these should be much more important in the case of an ion than a neutral molecule, since ions in solution tend to be surrounded by ionic atmospheres (Debye–Hückel effect). Now when a typical boron oxyacid forms a salt by addition of base, these two factors will act in opposition; the change in covalency of boron should tend to decrease quadrupole relaxation and so reduce the line width, whereas the acquisition of negative charge should tend to increase it. If, on the other hand, salt formation involves loss of a proton so that the boron atom remains planar and trivalent, one might expect the line-broadening effect of the charge to operate unopposed. One might therefore expect the change in line width on passing from neutral to alkaline solution to serve as an additional criterion of acid type; boron protic acids should show a much greater increase. Examination of Table I shows that this prediction holds rather spectacularly. The line widths for Lewis acids are usually less in

alkaline than in neutral solution and certainly show no significant increase with salt formation, whereas the line widths for the protic acids increase enormously on addition of alkali.

We can therefore conclude with some assurance that boric acid, the arylboronic acids V and VI, and boraphthalide (VII) behave as Lewis acids to hydroxide ion, while the hydroxyborazaro compounds I–III behave as protic acids. This difference can of course be attributed<sup>3</sup> to the aromatic nature of the latter compounds; addition of base to boron would destroy cyclic conjugation in the boron-containing ring.

The last of our hydroxy acids, 4-hydroxy-4,3-boroxarisoquinoline (VIII), is particularly interesting in this respect. Boroxaro compounds should be less aromatic than their nitrogen counterparts and this is known to be the case for the oxygen analog of I,<sup>10</sup> 10-hydroxy-10,9-boroxarophenanthrene (X). Nevertheless ultraviolet spectral data seemed to suggest unambiguously that X behaves as a protic acid, the aromaticity of the central ring still being sufficient to inhibit addition to boron; it is therefore of interest to see if the same is true of VIII. The ultraviolet spectrum of VIII is almost the same in alkali as in neutral solution, suggesting that VIII also behaves as a protic acid;<sup>11</sup> however, the results in Table I show that this tentative conclusion was incorrect, VIII behaving as a Lewis acid toward hydroxide ion. This is indicated both by the large upfield shift (25 ppm), and by the decrease in line width (290  $\rightarrow$  210 Hz), on passing from neutral to alkaline solution.

The chemical shifts listed in Table I are also of some general interest in connection with the problem of relating chemical shifts to structure. It will be noticed that the resonances for arylboronic acids appear downfield by *ca.* 10 ppm relative to boric acid, implying that replacement of hydroxyl by phenyl has a deshielding effect. Phillips, *et al.*,<sup>8</sup> have drawn attention to this surprising circumstance and have pointed out that it cannot be attributed to any effect of ring current or unsaturation, for the  $^{11}\text{B}$  chemical shifts of phenylboronic acid and *n*-butylboronic acid differ by less than 1 ppm. The effect seems to be related in some way to the presence of boron–carbon bonds, for replacing the B–OH group in III by methyl (to form VIII) leads to a further downfield shift of 6.7 ppm. The most likely explanation seems to lie in a strong magnetic anisotropy of the C–B bond, resulting in a net deshielding effect on the boron atom.

# The Neighboring Sulfonium Group in Ester Hydrolysis

Joseph Casanova, Jr., Newton D. Werner, and Hansruedi R. Kiefer

Contribution from the Department of Chemistry, California State College at Los Angeles, Los Angeles, California 90032. Received December 16, 1966

**Abstract:** The alkaline hydrolysis of methyl 2-dimethylsulfoniophenylacetate *p*-toluenesulfonate (*o*-5) proceeds 5.2 times faster than that of the 4 isomer (*p*-5). With a correction for steric effects, the ratio is 14. The 2-dimethylsulfonio ester is hydrolyzed 356 times faster than the 2-isopropyl ester, and the 4-dimethylsulfonio ester is hydrolyzed 25 times faster than the 4-isopropyl ester. From these data and proton resonance spectra, it is concluded that the neighboring sulfonium group in these compounds exhibits a small rate-enhancing effect on ester hydrolysis, probably *via* a field effect rather than by covalent bonding between sulfur and oxygen.

The role of neighboring functional groups in intramolecular nucleophilic catalysis of ester hydrolysis is clearly established and has been the topic of extensive researches.<sup>1</sup> The intervention of intramolecular electrophilic catalysis in alkaline ester hydrolysis has been advanced in the case of hydroxylic hydrogen,<sup>2</sup> and is thought to be of the general acid type. Such electrophilic catalysis has not been reported for other electrophiles, perhaps due to the paucity of functional groups which are potentially capable of serving in this capacity. The extensive distribution of sulfonium compounds in biological systems<sup>3</sup> and the well-documented propensity of sulfur for d orbital resonance<sup>4</sup> suggested that a neighboring sulfonium group might function as such an electrophilic group, capable of the intramolecular catalysis of alkaline ester hydrolysis, either by bonding with, or inducing polarization in the carbonyl group (a, a') or by stabilizing the tetrahedral intermediate (b, b') in ester hydrolysis, or both. Either effect should lead to a rate increase. The object of the work described in this paper was to prepare esters containing

sulfonium groups disposed in space so as to favor the incursion of such an effect and to examine the hydrolysis rates of these esters when compared to isomeric systems incapable of intramolecular catalysis.

## Results and Discussion

The substrates selected for this study were methyl 2-dimethylsulfoniophenylacetate *p*-toluenesulfonate (*o*-5) and the 4-substituted isomer (*p*-5). Their preparation is shown in Charts I and II. Their selection

Chart I

was predicated on the well-defined rigid geometry imparted by the aromatic ring and by the insulating effect of the  $\alpha$ -methylene group, which would operate so as to minimize direct resonance interaction between the sulfur and carbonyl carbon. Inductive effect differences between the *ortho* and *para* isomers should also be small, since the effect is already attenuated by four bonds in the *ortho* isomer.

In order to assess the magnitude of *ortho* steric effects, which are substantial in the case of substituted benzoates,<sup>5</sup> methyl 2- and 4-isopropyl phenylacetates were prepared and their hydrolytic behavior was examined under the same conditions as employed for the sulfonio esters. The assumption was made that an isopropyl group simulates a dimethylsulfonio group in steric requirement. The preparation of the isopropyl substituted esters is shown in Chart III.

## Chart II

## Chart III

Hydrolysis rates were measured titrimetrically at constant pH using 50% v/v aqueous dioxane as solvent. A plot of  $\log C_0/C_t$  vs. time gave a straight line for several half-lives. Rate constants were measured under conditions of similar ionic strength, although the effect of added salt was very small. A sample run is shown in Figure 1. The pseudo-first-order rate constants were calculated by the method of least squares using a simple computer program<sup>6</sup> and are shown in Table I. A graph of  $\log k$  vs. pH for the two sulfonio esters gave good parallel straight lines over the pH range 7.2–10.3 with a slope of 1.0 (Figure 2). Thus, both esters follow the simple

When the *ortho:para* rate ratio for sulfonium ester hydrolysis is corrected for steric rate retardation, which would operate in the hindered *ortho* ester but not in the

Figure 1.  $\log C_0/C_t$  vs. time for the hydrolysis of methyl 2-dimethylsulfoniophenylacetate *p*-toluenesulfonate in 50% aqueous dioxane at pH 7.17 and 69.5° (run 026).

*para*, by dividing by the *ortho:para* rate ratio obtained for the isopropyl esters (*o*-8 and *p*-8), the ratio becomes 14. Contrasted with the magnitude of rate acceleration values which have been observed for systems in which nucleophilic neighboring group assistance is thought to occur efficiently<sup>7</sup> ( $10^2$ – $10^6$ ), the enhanced reactivity in the present case is hardly significant.

To assess the importance of a neighboring sulfonium ion in stabilizing a negatively charged carboxyl derivative, the  $pK_a$  was measured for 2- and 4-dimethylsulfoniophenylacetic acids (*o*-3 and *p*-3). These values are shown in Table III. Although the resonance-stabilized car-

Table III. Acidity Constants of Carboxylic Acids Prepared in This Study, Measured in 45.0% w/w Dioxane–Water at 29°

<i>o</i> -3	4.07
<i>p</i> -3	4.82

boxylate anion with a delocalized negative charge must be a poor model for the anticipated tetrahedral intermediate with a full negative charge localized on one oxygen atom, both effects operate in the same direction and the difference in acidity between the two acids should give an indication of the importance of stabilization of the tetrahedral intermediate during ester hydrolysis. The *o*-sulfonium acid (*o*-3) is seen to be more than 100 times stronger an acid than the corresponding methylthio acid (*o*-2), whereas the ratio between the *para* acids (*p*-3 and *p*-2) is close to 10. However, the difference in acidity between *o*-3 and *p*-3 is only 0.75  $pK$  unit, which does not suggest considerable stabilization of the carboxylate anion by the neighboring sulfonium ion. In its ultimate form, stabilization could take the form of covalent bonding between the carboxylate anion and the sulfonium sulfur atom (c').

Figure 2. The pH-rate profile for the alkaline hydrolysis of methyl 4-dimethylsulfoniophenylacetate *p*-toluenesulfonate (*p*-5) and methyl 2-dimethylsulfoniophenylacetate *p*-toluenesulfonate (*o*-5).

The proton resonance spectra of the sulfonio acids (*o*- and *p*-3) in 2 *N* DCl and 2 *N* NaOD in  $D_2O$  were determined, and the chemical shift of the dimethylsulfonio protons was measured with respect to the chemical shift of the same protons in pure  $D_2O$ . If the covalent form (c') made a significant contribution to the structure of the anion, then the methyl protons should show a substantial increase in shielding as the medium was changed from acidic to basic, and the species present became the carboxylate anion. The results of these measurements are shown in Table IV. Although the *ortho* zwitterion shows a slightly greater shielding than the *para*, the magnitude of the difference does not warrant invoking structure c' as a significant contributing form.

Table IV. The Chemical Shift of the Dimethylsulfonio Protons of 4-Dimethylsulfoniophenylacetic Acid and 2-Dimethylsulfoniophenylacetic Acid Measured in 2 *N* HCl and 2 *N* NaOH

It might be anticipated that if the transition state for hydrolysis of *ortho* ester (*o*-5) involved covalent bonding to sulfur (b') this difference would be reflected in a more negative  $\Delta S^\ddagger$  for the *ortho* than for the *para* ester because of greater constraint in such a transition state. The activation parameters for the sulfonium esters were determined from the second-order rate constants for hydrolysis at pH 10.33 using rate measurements at four temperatures. The calculated values of  $E_a$  and  $\Delta S^\ddagger$  are shown in Table V. The near coincidence of both the activation energy and the activation entropy for the two sulfonio esters suggests again that the rate differences between the esters should not be attributed to any fundamental differences in the mode of reaction.

The magnitude and sign of the entropy of activation is itself very unusual and warrants comment. Most reactions which are bimolecular in the rate-controlling

**Table V.** Activation Parameters for the Hydrolysis of Methyl 2-Dimethylsulfoniophenylacetate *p*-Toluenesulfonate and Methyl 4-Dimethylsulfoniophenylacetate *p*-Toluenesulfonate at pH 10.33

step exhibit an entropy of activation of about  $-20$  eu.<sup>8</sup> Although the magnitude of the activation energy observed here is similar to that reported for many ester hydrolysis reactions, the entropy of activation is 15–30 eu greater than anticipated.<sup>9</sup> One interpretation of this result is that ester hydrolysis in the present case (both *ortho* and *para*) is not bimolecular in the rate-controlling step. A reasonable mechanism involving a ketene intermediate can be devised to accommodate that interpretation.<sup>10</sup>

Inductive and resonance stabilization of the enolate anion renders this mechanism an attractive possibility. Suggestions of the operation of this mechanism in the literature are rare.<sup>11</sup> A necessary condition for the intervention of this novel pathway is that the rate of exchange of  $\alpha$ -hydrogen be at least as fast as the over-all hydrolysis rate. This has been determined to be the case for the *para* ester *p*-3, for which  $k_x$  (exchange per hydrogen)/ $k_2$  (hydrolysis) is 8. Other experiments designed to test the interpretation stated above are in progress.

A recent report<sup>12</sup> of the kinetics of alkaline hydrolysis of several substituted ethyl acetates included the bro-

midate salt of ethyl dimethylsulfonium acetate. The rate differences observed were attributed largely to electrostatic effects of substituent charges and dipoles, rather than to inductive effects. The possibility of covalent bonding between sulfur and the carbonyl group of the ester was not discussed. Inductive effects were dismissed as small in the sulfur-substituted series, based on the questionable assumption that electronegativity differences should be small in the series  $RS^+(\text{CH}_3)_2$ ,  $RSCH_3$ , and  $RS^-$ . In addition, the data presented by these authors gives a straight line when plotted as  $\log k_2$  vs.  $\sigma^*$ . Under the circumstances we feel that it would be premature to dismiss an inductive effect as unimportant in the sulfonium salts.

The magnitude of the *ortho:para* ratio for the sulfonio esters is small enough so that it could be interpreted in terms of an inductive effect alone. This is contrary to our assumption at the onset of this study. To the extent that the hydrolysis of sulfonium esters *o*-5 and *p*-5 follows a normal hydrolytic sequence, a supposition to which some doubt has been raised here, it is evident that neighboring sulfonium sulfur exerts a surprisingly small electrophilic enhancement of the rate of ester hydrolysis.

## Experimental Section

***o*-Mercaptophenylacetic Acid (1).** This compound was prepared by the method of Pascal and Tarbell.<sup>13</sup> The acid did not crystallize and was used directly in the preparation of the sulfide. The yield was 22%.

**2-(Methylthio)phenylacetic Acid (*o*-2).** A solution of 4.0 g of *o*-mercaptophenylacetic acid in 15 ml of absolute ethanol was added slowly to a warm solution of 3.01 g (0.024 mole) of dimethyl sulfate in 15 ml of 33% aqueous sodium hydroxide and heated at reflux for 0.5 hr. The ethanol was removed *in vacuo*, and approximately 10 ml of water was added. The solution was acidified with 6 *N* HCl and solid appeared. The solid recrystallized from chloroform, 1.31 g (30%), mp 127–129°. An infrared spectrum in chloroform showed strong absorption at 1715  $\text{cm}^{-1}$  (s), 3600–2500  $\text{cm}^{-1}$  (m). An nmr spectrum in  $\text{CDCl}_3$  with tetramethylsilane as an internal standard showed a complex multiplet, centered at 7.32 ppm, a singlet at 3.86 ppm, and a singlet at 2.44 ppm with the area ratio 4:2:3, respectively.

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{O}_2\text{S}$ : C, 59.31; H, 5.53; S, 17.59. Found: C, 58.91; H, 5.55; S, 17.59.

**2-Dimethylsulfoniophenylacetic Acid *p*-Toluenesulfonate (*o*-3).** 2-(Methylthio)phenylacetic acid (0.5 g, 2.7 mmoles), 1.0 g (5.4 mmoles) of methyl *p*-toluenesulfonate (Eastman, distilled), and 5 ml of toluene (reagent grade, dried over sodium) were heated overnight. An oil separated and the toluene was decanted. The oil was crystallized by trituration with methanol. The white solid was twice recrystallized by dissolving it in acetone containing a few milliliters of ethanol and then adding ethyl acetate to give 0.28 g (27%) of white solid, mp 153.0–153.5°.

*Anal.* Calcd for  $\text{C}_{17}\text{H}_{20}\text{O}_5\text{S}_2$ : C, 55.41; H, 5.47; S, 17.40. Found: C, 55.38; H, 5.55; S, 17.22.

**4-(Methylthio)phenylacetic Acid (*p*-2).** This compound was prepared in 45% yield by the method of Elderfield and Burgess,<sup>14</sup> mp 93–95° (lit.<sup>14</sup> 94–95°).

**4-Dimethylsulfoniophenylacetic Acid *p*-Toluenesulfonate (*p*-3).** 4-(Methylthio)phenylacetic acid (1 g, 5.4 mmoles), 2.0 g (10.8 mmoles) of methyl *p*-toluenesulfonate (Eastman, distilled), and 10 ml of anhydrous toluene were refluxed for 6 hr. The solid which had formed was collected on a filter and washed with benzene. The solid was twice recrystallized from ethanol–ethyl acetate to give 0.80 g (41%) of white solid, mp 180–182°.

*Anal.* Calcd for  $\text{C}_{17}\text{H}_{20}\text{O}_5\text{S}_2$ : C, 55.41; H, 5.47; S, 17.40. Found: C, 55.47; H, 5.56; S, 17.08.

**$pK_a$  Determinations.** A standard solution of sodium hydroxide (0.0498 *N*) in 55.0% (by weight) of distilled water and 45.0% (by

(13) I. I. Pascal and D. S. Tarbell, *J. Am. Chem. Soc.*, **79**, 6015 (1957).

weight) of dioxane (purified by the Hess and Frahm method<sup>15</sup>) was the titrant. The general method of Albert and Serjeant<sup>16</sup> was used to determine the  $pK_a$  values. The sample was dissolved in 55.0% (by weight) of water and 45.0% (by weight) of dioxane. A Leeds and Northrup pH meter was used, and the meter was standardized with both phthalate buffer (pH 4.00) and phosphate buffer (pH 6.86) before and after the measurements. During the measurement of pH, prepurified nitrogen gas was bubbled through Fieser's solution,<sup>17</sup> reaction solvent, and into the cell. The calculation of the  $pK_a$  values was carried out as described elsewhere.<sup>18</sup> Corrections for the hydrogen ion concentration were applied.

**Methyl 4-(Methylthio)phenylacetate (*p*-4).** A solution of 5.5 g (20 mmoles) of 4-(methylthio)phenylacetic acid, 10 ml of methanol (reagent grade), 10 ml of 2,2-dimethoxypropane (Dow Chemical Co.), and a few milligrams of *p*-toluenesulfonic acid monohydrate was stirred overnight at room temperature. The solution was concentrated *in vacuo* and then taken up in chloroform and washed in sodium bicarbonate and saturated aqueous sodium chloride. The dried chloroform solution was concentrated to give a tan liquid. Distillation of this liquid gave 3.0 g (51%), bp 178–180° (0.5 mm) [lit.<sup>19</sup> 179–181° (3 mm)]. An infrared spectrum in chloroform showed no absorption between 3600 and 3200  $\text{cm}^{-1}$  and strong absorption at 1735  $\text{cm}^{-1}$ .

**Methyl 4-Dimethylsulfoniophenylacetate *p*-Toluenesulfonate (*p*-5).** Methyl ester *p*-4 (3 g, 0.015 mole) and methyl *p*-toluenesulfonate (3.6 g, 0.019 mole) (Eastman, distilled) were heated at 100° for 3 hr. After cooling to room temperature the reaction mixture solidified. The solid was first washed with ethyl ether and then collected on a filter. Recrystallization from dioxane-methanol gave 5.0 g (87%) of a white solid, mp 145–147°.

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{14}\text{O}_5\text{S}_2$ : C, 56.52; H, 5.80; S, 16.77. Found: C, 56.35; H, 5.80; S, 16.40.

**Methyl 2-(Methylthio)phenylacetate (*o*-4).** A solution of 3.7 g (0.020 mole) of 2-(methylthio)phenylacetic acid, 15 ml of absolute methanol, 10 ml of 2,2-dimethoxypropane (Dow Chemical Co.), and a few milligrams of *p*-toluenesulfonic acid monohydrate was heated at reflux for 4 hr. The dark solution was concentrated *in vacuo*, taken up in chloroform, and washed with sodium bicarbonate solution and saturated aqueous sodium chloride solution. The chloroform solution was dried and distilled to give 2.8 g (72%) bp 99–100° (0.75 mm);  $n_D^{20}$  1.5632. An infrared spectrum in chloroform showed no absorption between 3600 and 3200  $\text{cm}^{-1}$  and strong absorption at 1730  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{12}\text{O}_3\text{S}$ : C, 61.20; H, 6.16; S, 16.34. Found: C, 61.14; H, 6.08; S, 16.13.

**Methyl 2-Dimethylsulfoniophenylacetate *p*-Toluenesulfonate (*o*-5).** A solution of 2.8 g (0.014 mole) of methyl ester *o*-4 and 3.2 g (0.017 mole) of methyl *p*-toluenesulfonate (Eastman, distilled) was heated at 100° for 3 hr. The reaction mixture was cooled to room temperature and a solid formed which was washed with ethyl ether and collected on a filter. The white solid was recrystallized from 2-butanol to give 2.5 g (46%) of a white solid, mp 156–158°. A second crop of 1.2 g (22%) was obtained.

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{14}\text{O}_5\text{S}_2$ : C, 56.52; H, 5.80; S, 16.77. Found: C, 56.15; H, 5.74; S, 16.54.

**2- and 4-Isopropylbenzyl Bromides (*o*- and *p*-6).** Into a solution of 120 ml of (48%) HBr, 93 g of cumene, 39 g of paraformaldehyde, and 200 mg of red phosphorus, gaseous HBr was bubbled for 6 hr while the mixture was stirred vigorously. After 20 min the reaction mixture became hot and was cooled for 30 min in an ice bath until all paraformaldehyde was dissolved and no further exothermic reaction was observed. It was then held at 55° for 18 hr. The organic layer was separated, washed with water, and dried over  $\text{MgSO}_4$ .

Distillation at 64° (0.5 mm) yielded 141.8 g (77%) [lit.<sup>19</sup> bp 126–130° (20 mm)].

**2- and 4-Isopropylbenzyl Cyanides (*o*- and *p*-7).** Potassium cyanide (60 g) was dissolved with stirring in 70 ml of water. After addition of 60 ml of ethanol, the solution was cooled with ice and 140 g of the bromide (*o*- and *p*-6) in 60 ml of ethanol was added over a period of 30 min. The reaction mixture was then stirred at room temperature for 2 hr. The solid KBr was removed by filtra-

tion and the alcohol evaporated. The oily layer was washed with water and extracted with ether. The ether solution was dried over  $\text{MgSO}_4$  and evaporated. Distillation on a Vigreux column, 92° (0.5 mm), yielded 96.5 g (93%) of product.

**Methyl 2- and 4-Isopropylphenyl Acetates (*o*- and *p*-8).** The mixed cyanides (*o*- and *p*-7), 96.5 g, in 180 ml of methanol and 80 ml of concentrated sulfuric acid were refluxed for 20 hr. Water was added, and the resulting oil was extracted into ether, washed with 10%  $\text{NaHCO}_3$  and water, dried, and distilled, bp 68–83° (0.5 mm), 77 g (66%). This material was distilled on a spinning-band column and collected in three fractions (see Table VI). The first distillation fraction was separated by preparative glpc on a 10-ft Carbowax 20M column, 185°, and the esters (8) collected were redistilled.

Table VI

Bp, °C (0.5 mm)	Glpc, %		Wt, g
	<i>ortho</i>	<i>para</i>

96	15	85	40
96–98	6	94	15

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{14}\text{O}_2$  [*ortho*: bp 78° (1 mm)]: C, 74.96; H, 8.39. Found: C, 74.94; H, 8.43. Found [*para*: bp 80° (0.2 mm)]: C, 75.39; H, 8.51.

**Kinetics Procedure.** The dioxane used was commercial grade, purified by the method of Hess and Frahm.<sup>15</sup> Standard sodium hydroxide solutions were prepared in the reaction solvent so that the composition of the solvent would not be changed during the reaction. The concentration of the sodium hydroxide solution was between  $10^{-3}$  and  $10^{-2}$  N, so as to give about 2 ml volume change, depending on the rate of the hydrolysis reaction.

A solution (50 ml) of 50.0% (by volume) dioxane and 50.0% (by volume) water was pipetted into a jacketed reaction cell which was equipped with a Beckman amber glass electrode and a Beckman silver chloride reference electrode, an automatic buret, the tip of which was immersed in the reaction solution, and a water condenser. The reaction solution was stirred magnetically under an atmosphere of prepurified nitrogen. The solvent was allowed to equilibrate thermally for 1 hr in the cell. During the equilibration period, the pH of the solution was adjusted to the desired regulation point by the addition of a very small amount of either acid or base. Either 100 or 50 mg of sample was added to the reaction cell.

Base was added automatically in small increments to maintain the pH constant to  $\pm 0.04$  unit. The buret was driven by a relay which was activated by imbalance in a 1:10 scale-expanded pH meter. The results were recorded automatically on a chart. First-order rate constants were calculated by the method of least squares using an IBM 1620 computer.<sup>6</sup>

The nature of the hydrolysis products was confirmed by carrying out several reactions in nmr tubes and identifying methanol and the carboxylic acids which formed by their characteristic spectra.

**$\alpha$ -Methylene Exchange and Hydrolysis Rates by Nmr.** A sample of *p*-5 (54.7 mg, 0.143 mmole) was dissolved in 0.50 ml of  $\text{K}_2\text{BO}_3\text{--H}_3\text{BO}_3$  buffer in  $\text{D}_2\text{O}$  (pH 10.69), and the sample was immediately frozen to  $-78^\circ$ . The proton resonance spectrum was followed at 36.5° as a function of time. The  $\alpha$ -methylene exchange rate was calculated by comparing one-half of the methylene peak integral to an internal standard (3 H from the *p*-toluenesulfonate anion). A plot of  $\log [0.5(\text{area CH}_2)/\text{area CH}_3(\text{tosyl})]$  vs. time gave a straight line, from which a pseudo-first-order rate constant for  $\alpha$ -hydrogen exchange was obtained. The result is shown below. By determining the area under the ester  $\text{CH}_3$  peak, relative to that under the tosyl  $\text{CH}_3$  peak during the reaction, or by plotting a graph of  $\log [\text{area CH}_3(\text{ester})/(\text{area CH}_3(\text{ester}) + \text{area CH}_3(\text{methanol}))]$  vs. time, a straight line could be obtained which measured the over-all hy-

## Dimethyl Sulfoxide-Acid Anhydride Mixtures for the Oxidation of Alcohols

J. Donald Albright and Leon Goldman

*Contribution from the Organic Chemical Research Section, Lederle Laboratories, A Division of American Cyanamid Company, Pearl River, New York 10965.*

*Received December 22, 1966*

**Abstract:** Oxidation of alcohols with dimethyl sulfoxide and acetic anhydride is reported. The conversion of secondary hydroxyl functions to ketones in a variety of alkaloids and steroids occurs in moderate to excellent yields. The dimethyl sulfoxide-acetic anhydride oxidation procedure is particularly useful for oxidation of sterically hindered hydroxyl groups and for oxidation of hydroxyl functions in sensitive molecules such as indole alkaloids. The mechanism of oxidation is discussed. By-products often formed are methylthiomethyl ethers of the starting alcohols.

Our continued interest in improved methods for the oxidation of secondary hydroxyl groups of indole alkaloids<sup>1</sup> to ketones led to the discovery of a novel method of oxidation of alcohols to their corresponding carbonyl derivatives with dimethyl sulfoxide (DMSO) and acetic anhydride.<sup>2</sup> Oxidation of alcohols with acetic anhydride-DMSO is a mild oxidative method and is particularly useful with indole alkaloids which are sensitive to nonselective oxidizing reagents. In addition this procedure gives good yields with sterically hindered hydroxyl groups and has been applied to a number of steroids. However, it is obvious that this method will fail in cases where alcohols are rapidly acetylated under the conditions of the reaction, for O-acetylation will then effectively compete with oxidation.

In general, the procedure consists of stirring a solution of the alcohol in a mixture of DMSO and acetic anhydride for 15-24 hr at room temperature. Dimethyl sulfoxide has been used as both solvent and reagent, although there is no reason to believe that an inert diluent is deleterious. In our original experiments a ratio of 20 moles of acetic anhydride to 1 mole of alcohol was employed; however, such a large excess of acetic anhydride is not necessary. Successful oxidations have been carried out with 3-5 moles of anhydride per mole of alcohol.

Optimal conditions for the reaction and variations which could be employed were determined using yohimbine (1) as substrate. The reaction of 1 (1 mmole), 3 ml of DMSO, and 2 ml (*ca.* 20 mmoles) of acetic anhydride was followed by periodically removing aliquots

and determining the extent of reaction by thin layer chromatography (tlc) on silica gel. In 4-5 hr the reaction was approximately 50% complete and in 12 hr no more starting material remained. Yohimbine<sup>3</sup> (3) was isolated in 80% yield at the end of this time. No reduction in the yield was observed on decreasing the molar ratio of alcohol 1 to acetic anhydride to 1:5.

Certain other acid anhydrides can be used in place of acetic anhydride. Benzoic anhydride (17 moles) and yohimbine (1 mole) in DMSO at room temperature for 22 hr afforded 82% of  $\beta$ -keto ester 3. However trifluoroacetic anhydride and *p*-toluenesulfonic anhydride were not effective. Based on plausible mechanistic considerations (*vide infra*) anhydrides unreactive to DMSO should be unsatisfactory as should overly reactive ones. Phosphorus pentoxide<sup>4</sup> and polyphosphoric acid were studied briefly with the following results. Yohimbine (1) (1 mole) and phosphorus pentoxide (1 mole) in DMSO at 65° for 18 hr gave yohimbine-3-one (3) in 45% yield. Polyphosphoric acid and 1 at room temperature for 41 hr afforded 3 in 51%

(4) The oxidation of alcohols to ketones in the carbohydrate field with DMSO-phosphorus pentoxide has been described recently: K. Onodera, S. Hirano, and N. Kashimura, *J. Am. Chem. Soc.*, **87**, 4651 (1965).

Oxidation of testosterone with polyphosphoric acid in DMSO at room temperature was unsatisfactory. Oxidation of ajmaline with phosphorus pentoxide<sup>1</sup> at 65° (multiplicity of products on tlc).

Use of sulfoxides other than DMSO was briefly mentioned. For example, with tetramethylene sulfoxide, yohimbine (1) (1 mole) and acetic anhydride (21 moles) gave yohimbine (3) in 80% yield, while diphenyl sulfoxide gave no oxidation. These limited results showed that only sulfoxides reactive to acid anhydrides<sup>2</sup> will give oxidation as anticipated from mechanistic considerations.

Yohimbine (1) undergoes oxidation with acetic anhydride to give yohimbine (3) in 80% yields, this method constitutes a superior procedure for the preparation of 3.<sup>6,7</sup> In the oxidation of 1 to 3 a small amount of a second product was isolated. From a large-scale oxidation of 1 the minor product was isolated and identified as methyl 17 $\alpha$ -(methylthio)methoxy-yohimban-16 $\alpha$ -carboxylate (4). Nmr spectrum (in  $\delta$ ) of 4, with singlets at 2.10 (3H,  $\text{OCH}_3$ ) and 3.73 ( $\text{OCH}_2\text{S}$ ) and an AB quartet centered at 4.5 ( $\text{OCH}_2\text{S}$ ), demonstrated the presence of the methylthiomethoxy group and established the structure. Application of the DMSO-acetic anhydride oxidation procedure to a variety of substrates was undertaken to further define the utility of the method and to obtain information bearing on the mechanism of the reaction.  $\beta$ -Yohimbine (2), which differs from 1 only in the configuration of the C-17 hydroxyl group (equa-

torial in 2 vs. axial in 1), was completely converted to a 50:50 mixture (determined by tlc and integration of pmr signals) of ketone 3 and methylthiomethoxy derivative 5. Chromatography on silica gel afforded 25% of 3 and 18% of 5. In a similar manner  $\alpha$ -yohimbine (6) (equatorial hydroxyl) afforded equal amounts of two components which were separated by chromatography to give 40% of crude methyl 17-hydroxy-yohimban-16-ene-16-carboxylate<sup>1</sup> (7) and 10% of methylthiomethoxy derivative 8.

Methyl reserpate (9) (equatorial hydroxyl) afforded 33% of methyl ketoreserpate<sup>8</sup> (10) and 11% of methyl reserpate methylthiomethoxy derivative (11).

Ajmaline (12) has two possible sites for oxidation, the C-17 hydroxyl and the C-21 carbinolamine hydroxyl. However, oxidation with DMSO-acetic anhydride, followed by treatment of the product with methanolic sodium hydroxide to hydrolyze O-acetates, gave ajmalidine<sup>9</sup> (13) (52% as a glass) and methylthiomethoxy derivative 14 (10%). Difficulties were encountered in crystallizing ajmalidine. From the glass crystalline 13 (4% from 12) was obtained with the expected spectral

(infrared, ultraviolet, pmr) properties. Thin layer chromatography and pmr spectral data indicated that both the glass and the crystalline material were identical. Furthermore, treatment of the glass with acetic anhydride-pyridine gave, in 68% yield, the same O-acetate 15 as was obtained from crystalline 13. That ajmalidine O-acetate (15) is one of the original products of the oxidation was shown by isolation of 15 when the methanolic base treatment was eliminated from the product work-up. On a larger scale (0.04 mole) oxidation of ajmaline (12), crystalline ajmalidine (13) was obtained in 25% yield along with 18% of methylthiomethoxy derivative 14.

<sup>1</sup> Reactivity of sulfoxides to anhydrides (Pummerer rearrangement). R. Pummerer, *Ber.*, **43**, 1401 (1910); L. Horner and P. Kaiser, *ibid.*, **19** (1959).

<sup>2</sup> Oppenauer oxidation of yohimbine (1) gives yohimbine (3) in 80% yield.<sup>3</sup>

<sup>3</sup> Yohimbine (1) was oxidized to 3 (80%) with dicyclohexylcarbodiimide in DMSO, and phosphoric acid.<sup>4</sup>

Oxidation<sup>10</sup> of galanthamine (16), an allylic alcohol, with DMSO and acetic anhydride gave narwedine<sup>11</sup> (17) in moderate yield, while oxidation of codeine to codeinone was unsuccessful.

The oxidation of a number of steroidal alcohols was studied. Tlc showed that testosterone (18) is oxidized with DMSO-acetic anhydride to give approximately 70% of 4-androstene-3,17-dione<sup>12</sup> (19) and 30% of

17β-[(methylthio)methoxy]-4-androsten-3-one<sup>13</sup> (20). Chromatography afforded 34% of 19 and 8% of 20. The effect of the configuration of the hydroxyl group on the product composition was vividly demonstrated by comparison of the oxidation of hydrocortisone 21-acetate (21) (axial 11β-hydroxyl) and 11α-hydroxyprogesterone (23) (equatorial hydroxyl). The sterically hindered 11β-hydroxyl group of 21 was oxidized smoothly but slowly (92 hr at room temperature) to give cortisone 21-acetate<sup>14</sup> (22) (53% by direct crystallization of the product). In contrast, 11α-hydroxyprogesterone (23) afforded, after partition chromatography, two major components, the larger of which was a gum (56%) identified by its pmr spectrum as methylthiomethoxy derivative 25. The second component (30% as glass) was crystallized to give 11-ketoprogesterone<sup>15</sup> (24) in 13% yield. It is of interest that oxidation of 23 with dicyclohexylcarbodiimide (DCC), DMSO, and pyridinium trifluoroacetate has been reported by Pfitzner and Moffatt<sup>16</sup> to proceed smoothly while no oxidation was observed with 21.

Some conclusions about the mechanism of oxidation of alcohols with DMSO and acid anhydrides can be

drawn. Carboxylic acid anhydrides are known to react with sulfoxides to give α-acyloxy sulfides<sup>5,17</sup> and recently carboxylic acids have been shown to react with phosphorus pentoxide and DMSO to give α-acyloxy sulfides.<sup>18</sup> The reaction of thionyl chloride and acid chlorides such as benzoyl chloride with sulfoxides has been shown<sup>19</sup> to give α-chloro sulfides. All these reactions have one feature in common in that they are best visualized as proceeding by reaction of an electrophile on the electronegative oxygen atom of the sulfoxide to give intermediate oxysulfonium salts of type 26.

We were led to consider an oxidation sequence involving activation of DMSO to give an intermediate of type 26 by the evidence for such intermediates and by reasoning that they might react with an alcohol *in situ*. Such SN2 displacements with alkoxysulfonium salts<sup>20</sup> have been demonstrated recently. Alkoxysulfonium salt 26 (wherein R = alkyl or cycloalkyl) could be reasonably expected to collapse in the presence of a base to give carbonyl products. The oxidation of α-bromoketones and alkyl tosylates with DMSO and base is based on similar mechanistic principles.<sup>21</sup> The sequence of reactions in Chart I can be considered for the oxidation of alcohols with DMSO-acetic anhydride. The acyloxysulfonium salt 27 is first formed, and nucleophilic attack of an alcohol on the positively charged sulfur atom of 27 with back-side displacement of acetate ion occurs to give alkoxysulfonium salt 29. Base-promoted removal of a proton from the methyl group of 29<sup>22</sup> then gives the sulfur stabilized ylid 33 which, through a cyclic transition state, collapses to give

 (22) See ref 20 for the reactions of alkoxysulfonium salts with alkoxides.

amounts of acetic anhydride and DMSO leads to *ca.* 65% of methylthiomethoxy derivative **20** after 6 days at room temperature. In addition, testosterone O-acetate and 4-androstene-3,17-dione (**19**) were formed as evidenced by tlc.

The difference in product composition observed between compounds with an axial or equatorial hydroxyl group deserves further comment. The increased amounts of methylthiomethoxy derivative with compounds having an equatorial hydroxyl group may be explained on the basis of two independent pathways, one for oxidation (*via* intermediates **29** or **30** and ylid **33**) and one for methyl thiomethyl ether formation (*via* ion pair **28**). It is then necessary to postulate that the less hindered equatorial alcohol reacts sufficiently faster with ion pair **28** than an axial alcohol due to steric factors. If ylid **33** is the intermediate for both oxidation and ether formation and the rate-determining steps are collapse of ylid with abstraction of the hydrogen on the carbinol carbon and rearrangement, a faster rate of oxidation of sterically hindered hydroxyl groups (steric assistance) would explain the fact that axial alcohols give more ketone and less ether derivative. A faster rate of oxidation of sterically hindered hydroxyl groups has been observed in chromic acid oxidations of steroidal alcohols<sup>27</sup> and these results were rationalized in terms of steric assistance.<sup>27</sup>

Without definitive rate data no conclusive choice between alternative mechanisms can be made. However, we believe methylthiomethoxy derivatives **31** are formed in a pathway independent of the oxidative sequence rather than by rearrangement of ylid **33** (*via* ion pair **32**). This belief rests mainly on the fact that little rearrangement of ylids of type **33** is observed in oxidations with DMSO, DCC, and phosphoric acid.<sup>1,13,16,23</sup>

The fact that trifluoroacetic anhydride and *p*-toluenesulfonic anhydride were unsatisfactory was mentioned previously and is readily understood on the basis of mechanistic considerations. For successful oxidations the intermediate acyloxysulfonium salt must be stable enough and present in sufficient concentration to allow nucleophilic attack by an alcohol to occur. With a very reactive anhydride, the acyloxysulfonium salt will rearrange (Pummerer reaction) too rapidly to allow subsequent reactions with it. Experimentally trifluoroacetic anhydride reacts violently with DMSO at room temperature. Probably for similar reasons a mixture of 1-chloro-N,N-diethyl-N'-propylformamidine<sup>28</sup> (**39**) and DMSO failed to oxidize testosterone. Alcohols react rapidly with chloroformamidine **38** and, therefore, intermediate **39** must be preformed. However, **39** may go on to other products too rapidly for subsequent reaction with an alcohol.

(28) Prepared by R. B. Conrow of these laboratories from N,N-diethyl-N'-propylurea and phosgene.

Further evidence that oxidations of alcohols by reagents prepared from mixtures of DMSO and suitable electrophiles proceeds *via* oxy-sulfonium salts, and that this is a general phenomenon was provided by experiments with <sup>18</sup>O-labeled alcohols. Oxidation of benzhydrol-<sup>18</sup>O (4.8% <sup>18</sup>O) with DCC, DMSO, and phosphoric acid gave unlabeled N,N'-dicyclohexylurea and 42% of the <sup>18</sup>O was found in the benzophenone isolated.<sup>29</sup> Oxidation of ethanol-<sup>18</sup>O (1.9% <sup>18</sup>O) afforded N,N'-dicyclohexylurea with only 16% of <sup>18</sup>O label.<sup>30</sup> In addition pseudourea **40**<sup>31</sup> was unaffected by the oxidizing reagent. These results indicate that DCC and DMSO interact to give sulfonium salt **41** which reacts

with alcohols to give alkoxy-sulfonium salts. Similar conclusions have been reached by Fenselau and Moffatt.<sup>23</sup>

Testosterone was found to be oxidized to 4-androstene-3,17-dione by a mixture of ethoxyacetylene, DMSO, pyridine, and phosphoric acid. Mechanistically the reaction may be illustrated as follows.

Protonation of ethoxyacetylene followed by reaction with DMSO gives intermediate **42** which then reacts with an alcohol. Tlc demonstrated that no testosterone O-acetate was formed in the reaction.

## Experimental Section

All melting points were taken on a Mel-Temp apparatus and are uncorrected. Samples for analysis were dried *in vacuo* over phosphorus pentoxide at 100° for 18–24 hr. Ultraviolet absorption spectra were measured on a Cary recording spectrophotometer. Infrared spectra were determined on a Perkin-Elmer spectrophotometer (Model 21). Pmr spectra were determined with a Varian Model A-60 spectrometer in deuterated chloroform or deuterated dimethyl sulfoxide; chemical shifts ( $\delta$ ) are in parts per million

(29) Per cent <sup>18</sup>O was determined by mass spectral analysis. Partial loss of label in the benzophenone probably resulted from exchange with solvent during aqueous acidic work-up.

(30) If ethanol were added to the DCC the N,N'-dicyclohexylurea should have been extensively labeled with <sup>18</sup>O. The small incorporation of label may have occurred from reaction of DCC with water-<sup>18</sup>O produced by aldol condensation of the acetaldehyde-<sup>18</sup>O formed in the oxidation.

(31) Prepared by the method of E. Schmidt and F. Moosmüller, *Ann.*, **597**, 235 (1955); E. Schmidt and W. Carl, *ibid.*, **639**, 24 (1961).

relative to internal tetramethylsilane. Concentrations were carried out *in vacuo*. Dimethyl sulfoxide was dried over Molecular Sieves (Type 4A, Fisher). Per cent  $^{18}\text{O}$  in labeled compounds was determined by mass spectral analysis. The  $^{18}\text{O}$  labeled water was purchased from Yeda Research and Development Co., Ltd. (affiliated with Weizmann Institute of Science), Rehovoth, Israel.

**Oxidation of Yohimbine (1) to Yohimbine (3).** A. With DMSO and Acetic Anhydride. To a mixture of 886 g of yohimbine (1) and 7.55 l. of dry dimethyl sulfoxide was added 5.05 l. of acetic anhydride. The mixture was stirred at room temperature for 18 hr. The mixture was diluted with 16.8 l. of ethanol, stirred for 1 hr, and diluted with 4.2 l. of water. Concentrated ammonium hydroxide (11 l.) was added while maintaining the temperature at 15–30° by cooling and the mixture was then diluted with 16.8 l. of water. Filtration gave a solid which was washed with water and dried to give 818 g (93%) of tan crystals, mp 248–250° dec. This was slurried twice with 4 l. of ethanol and filtered to give 742 g (84%) of 3, mp 253–254° dec; lit.<sup>3</sup> mp 243–249°.

The filtrate from the first slurry with 4 l. of ethanol was concentrated to give a dark colored gum. The gum was dissolved in chloroform–acetone–ethanol (6:3:1) and filtered through synthetic magnesia silica gel, the filter cake was washed with acetone, and the combined filtrates were concentrated to give 40 g of dark gum. The gum (20 g) was chromatographed on a column of 300 g of silica gel using chloroform–ethanol (99.3:0.7) as eluting solvent and 250-ml cuts were collected. Evaporation of cuts 5–11 gave the product as a glass. The combined glass from two column purifications was crystallized from methanol to give 6.95 g (0.7%) of methyl 17-[(methylthio)methoxy]yohimbane-16 $\alpha$ -carboxylate (4) as tan crystals, mp 195–198°. On standing the mother liquors gave a second crop (2.7 g, 0.3%) of yellow crystals, mp 195–198°. Recrystallization of 2.0 g from 20 ml of methanol gave 1.2 g of off-white crystals of 4, mp 198–200°;  $[\alpha]_D^{25} -164^\circ$  (c 1.03, pyridine); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  2.10 (SCH<sub>3</sub>) and 3.73 (OCH<sub>3</sub>); AB quartet centered at  $\delta$  4.62 ( $J_{AB} = 12$  cps) (OCH<sub>2</sub>S);  $\nu_{\text{max}}^{\text{KBr}}$  1724 (s), 1156 (s), 1041 cm<sup>-1</sup> (s).

Anal. Calcd for C<sub>23</sub>H<sub>30</sub>N<sub>2</sub>O<sub>5</sub>S: C, 66.6; H, 7.30; N, 6.76; S, 7.74. Found: C, 66.8; H, 6.99; N, 6.89; S, 7.74.

B. With DMSO and Benzoic Anhydride. A mixture of 2.12 g (0.0060 mole) of 1, 22.6 g (0.10 mole) of benzoic anhydride, and 20 ml of dry dimethyl sulfoxide was allowed to stand at room temperature for 22 hr. The mixture was diluted with 10 ml of water and 50 ml of ethanol and allowed to stand 30 min. The mixture was chilled by means of an ice bath and made basic with concentrated ammonium hydroxide. After diluting with 75 ml of water, the solid was collected by filtration and washed with water and with ether to give 1.73 g (82%) of 3 as light tan needles, mp 253–256° dec.

C. With Tetramethylene Sulfoxide and Acetic Anhydride. A mixture of 0.708 g (0.0020 mole) of 1, 10 ml of tetramethylene sulfoxide, and 4 ml of acetic anhydride was allowed to stand at room temperature for 21 hr. The solution was poured into 20 ml of ethanol, chilled, and made basic with concentrated ammonium hydroxide. The mixture was diluted with 25 ml of water and filtered to give 0.57 g (80%) of 3 as tan crystals, mp 250–253° dec.

D. With DMSO and Polyphosphoric Acid. A mixture of 1.8 g of polyphosphoric acid (Matheson Coleman and Bell, 82–84% P<sub>2</sub>O<sub>5</sub>), 0.708 g of 1, and 6 ml of dry dimethyl sulfoxide was warmed on a steam bath until the solid dissolved, and the solution was then stirred at room temperature for 41 hr. The resulting solution was diluted with 25 ml of ethanol and 5 ml of water, chilled, and made basic with concentrated ammonium hydroxide. The chilled mixture was diluted with 30 ml of water and filtered, and the precipitate was washed twice with 25-ml portions of water. The solid was then washed with ether to give 0.36 g (51%) of 3 as tan crystals, mp 239–243° dec. Recrystallization from ethanol–chloroform gave the product as tan crystals, mp 250–253° dec.

E. With DMSO and Phosphorus Pentoxide. To a solution of 1.06 g (0.0030 mole) of 1 in 10 ml of dry dimethyl sulfoxide was added 0.425 g (0.0030 mole) of phosphorus pentoxide. The solution was heated at 65° for 18 hr under nitrogen. The mixture was poured onto ice and made basic with concentrated ammonium hydroxide, and the resulting solid was removed by filtration and washed with water. The partially dried solid was dissolved in chloroform–ethanol (6:4) and filtered through Florisil. The filter cake was washed with chloroform–ethanol (9:1), and the filtrate was concentrated. The residue was triturated with ethanol, and the crystals were removed by filtration and washed with ether to give 0.48 g (45%) of 3 as yellow crystals, mp 240–243° dec.

**Oxidation of  $\beta$ -Yohimbine (2) to Yohimbine (3).** A mixture of 5.30 g of 2, 45 ml of dry dimethyl sulfoxide, and 30 ml of acetic anhydride was allowed to stand at room temperature for 19.5 hr under an atmosphere of nitrogen. The solution was diluted with 100 ml of ethanol and 10 ml of water, chilled, and made basic with concentrated ammonium hydroxide. The chilled mixture was diluted with 125 ml of water and filtered; the precipitate was washed with water to give 4.35 g of tan crystals. Chromatography of the product over silica gel gave, on elution with chloroform–methanol (99.5:0.5), a glass which was crystallized from methanol to yield 1.1 g (18%) of methyl 17-[(methylthio)methoxy]yohimbane-16 $\alpha$ -carboxylate (5) as colorless crystals, mp 167–169°. Recrystallization from methanol gave 0.7 g of 5, mp 189–190°;  $[\alpha]_D^{25} -80^\circ$  (c 1.0, pyridine); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  2.10 (SCH<sub>3</sub>), 3.78 (OCH<sub>3</sub>), and 4.62 (OCH<sub>2</sub>S);  $\nu_{\text{max}}^{\text{KBr}}$  1736 (s), 1064 (s), and 1047 cm<sup>-1</sup> (s) (sh).

Anal. Calcd for C<sub>23</sub>H<sub>30</sub>N<sub>2</sub>O<sub>5</sub>S: C, 66.6; H, 7.30; N, 6.76; S, 7.74. Found: C, 66.5; H, 7.47; N, 6.71; S, 7.36.

Further elution of the column with chloroform–methanol (99.5:0.5) afforded, after recrystallization from acetone–chloroform (80:20), 1.4 g (25%) of 3, mp 255–258°.

**Oxidation of  $\alpha$ -Yohimbine (6) to Methyl 17-Hydroxyalloyohimbane-16-ene-16-carboxylate (7).** A mixture of 2.12 g of 6, 25 ml of dry dimethyl sulfoxide, and 4.0 ml of acetic anhydride was stirred at room temperature for 21 hr. The mixture was poured onto 60 g of ice and 10 ml of water and made basic with concentrated ammonium hydroxide. The solid which separated was removed by filtration and washed with water. The dry solid was dissolved in ether and filtered through 10 g of synthetic magnesia silica gel. The filter cake was washed with ether and the combined filtrates were concentrated to give 2.10 g of a pale orange glass. Chromatography of 4.1 g of the glass over 200 g of silica gel gave in the first fractions, on elution with chloroform–ethanol (99.5:0.5), a glass which was crystallized from methanol to yield 0.48 g (10%) of methyl 17-[(methylthio)methoxy]alloyohimbane-16 $\beta$ -carboxylate (8) as tan crystals; melting point changes above 92° to a viscous mass which slowly liquefies. Recrystallization from methanol gave colorless crystals of 8 hemihydrate, melting point changes to viscous mass above 100° which slowly liquefies;  $[\alpha]_D^{25} +25^\circ$  (c 1.0, pyridine); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  2.10 (SCH<sub>3</sub>), 3.76 (C(=O)-OCH<sub>3</sub>), and 4.62 (OCH<sub>2</sub>S);  $\nu_{\text{max}}^{\text{KBr}}$  1724 (s) and 1064 cm<sup>-1</sup> (s).

Anal. Calcd for C<sub>23</sub>H<sub>30</sub>N<sub>2</sub>O<sub>5</sub>S·0.5H<sub>2</sub>O: C, 65.2; H, 7.38; N, 6.61; S, 7.57. Found: C, 65.5, 65.0; H, 7.76, 7.05; N, 6.74; S, 7.62.

Further elution of the column with chloroform–ethanol (99.5:0.5) afforded 1.8 g (40%) of 7 as a glass which was crystallized from methanol to give 0.67 g of tan crystals, mp 176–179° dec; lit.<sup>1</sup> mp 185–188° dec.

**Oxidation of Methyl Reserpate (9) to Methyl Ketoreserpate (10).** A mixture of 8.29 g of 9, 60 ml of dry dimethyl sulfoxide, and 40 ml of acetic anhydride was stirred at room temperature for 20 hr. The mixture was poured onto 350 g of ice and made basic with 10 N sodium hydroxide. The mixture was extracted with 250 ml and with two 100-ml portions of dichloromethane. The combined extracts were washed with water, dried over magnesium sulfate, and concentrated. The residue was suspended in ethanol and concentrated nearly to dryness. The residue was triturated with ether and filtered to give 5.17 g of off-white crystals. The ether filtrate was concentrated, and the residue was triturated with ether and filtered to give 2.2 g of solid. Trituration with 15 ml of hot ethanol and filtration afforded 1.81 g (22%) of 10 as tan crystals, mp 229–231° dec; lit.<sup>8</sup> mp 241–242° dec.

The 5.17 g of solid from above was chromatographed over 250 g of silica gel with chloroform–ethanol (96:4). The first fractions afforded 1.45 g (15%) of methyl reserpate methylthiomethyl ether (11) which was recrystallized from methanol to give 1.0 g (11%) as off-white crystals, mp 248–252° dec;  $[\alpha]_D^{25} -81^\circ$  (c 1.1, pyridine); pmr (CDCl<sub>3</sub>–DMSO-*d*<sub>6</sub>) singlets at  $\delta$  2.15 (SCH<sub>3</sub>), 3.53 (OCH<sub>3</sub>), 3.78 (two OCH<sub>3</sub>), and 4.73 (OCH<sub>2</sub>S);  $\nu_{\text{max}}^{\text{KBr}}$  1736 (s), 1151 (s), 1058 cm<sup>-1</sup> (s).

Anal. Calcd for C<sub>25</sub>H<sub>34</sub>N<sub>2</sub>O<sub>5</sub>S: C, 63.3; H, 7.22; N, 5.90; S, 6.76. Found: C, 63.1; H, 7.28; N, 6.18; S, 6.74.

The latter fractions from the column afforded an additional 0.65 g (11%) of 10 as off-white crystals, mp 229–231° dec.

**Oxidation of Ajmaline (12) to Ajmalidine (13).** A. A mixture of 7.17 g of 12, 60 ml of dry dimethyl sulfoxide, and 40 ml of acetic anhydride was allowed to stand at room temperature for 18 hr. The solution was poured onto 250 g of ice, and the chilled mixture was made basic with concentrated ammonium hydroxide and extracted with dichloromethane. The extract was washed with water,

dried over magnesium sulfate, and concentrated to give a gum. The gum was dissolved in 50 ml of hot ethanol, and the solution was diluted with 10 ml of water and 2.5 ml of 10 *N* sodium hydroxide. The solution was heated on a steam bath for 45 min, and the solvent was then removed under reduced pressure. Ethanol was added, and the solvent was again removed. The residue was triturated with water and filtered to give 6.1 g of solid. Chromatography of the solid over silica gel with chloroform-methanol (98:2) as eluent gave 3.4 g (52%) of 13 as a colorless glass which was crystallized from acetone to give 0.26 g (4%) of colorless crystals, mp 240–243°; lit.<sup>14</sup> mp 241–242°;  $[\alpha]^{25}_D$  –80° (c 1.0, acetic acid);  $\nu^{KBr}_{max}$  1742 (s) and 1616  $cm^{-1}$  (m).

*Anal.* Calcd for  $C_{20}H_{24}N_2O_2$ : C, 74.0; H, 7.46; N, 8.64. Found: C, 73.7; H, 7.76; N, 8.63.

The mother liquors from crystalline 13 were evaporated to a glass which was acetylated in the next experiment.

Further elution of the column with chloroform-methanol (98:2) gave 0.80 g (10%) of 17 $\beta$ -[(methylthio)methoxy]-21 $\alpha$ -ajmalaninol (14) as colorless crystals, mp 145–147°. Recrystallization from methanol afforded 0.45 g of colorless crystals, mp 148–150°;  $[\alpha]^{25}_D$  –9.8° (c 1.0, pyridine); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  2.20 (SCH<sub>3</sub>) and 2.77 (NCH<sub>3</sub>); AB quartet at  $\delta$  4.73 ( $J_{AB}$  = 12 cps) (OCH<sub>2</sub>S);  $\nu^{KBr}_{max}$  1605 (m) and 1047  $cm^{-1}$  (s).

*Anal.* Calcd for  $C_{22}H_{30}N_2O_2 \cdot 0.25H_2O$ : C, 67.6; H, 7.86; N, 7.16; S, 8.20. Found: C, 67.3; H, 8.04; N, 7.00; S, 7.97.

**B.** In a similar manner 14.34 g (0.040 mole) of 12 was oxidized and the product chromatographed over 350 g of silica gel (200-mL cuts) with the eluents chloroform-ethanol (99.3:0.7) (5.2 l), chloroform-ethanol (98.3:1.7) (1 l), and chloroform-ethanol (97:3) (3 l). The solid from fractions 13–33 was crystallized from methanol to give 3.5 g (25%) of 13 as colorless crystals, mp 240–243°. The solid from fractions 40–50 were crystallized from methanol to give 2.3 g (15%) of 14, mp 147–150°.

In another oxidation of 12 the crude product, extracted with dichloromethane from the basified (with ammonium hydroxide) reaction mixture, gave crystals of ajmalidine O-acetate (15), mp 209–211°.

**Ajmalidine O-Acetate (15).** Ajmalidine (13) (1.8 g of glass obtained from mother liquors of crystalline 13; see part A of preceding experiment) was dissolved in 5 ml of dry pyridine and 2 ml of acetic anhydride. The solution was allowed to stand for 19 hr at room temperature and then poured onto 35 g of ice. After standing 2 hr the mixture was made slightly basic with concentrated ammonium hydroxide and filtered. The solid was washed thoroughly with water and dried to give 1.4 g (68%) of 15 as off-white crystals, mp 208–213°. Recrystallization from ethanol gave 0.80 g of 15 as colorless needles, mp 218–220°;  $[\alpha]^{25}_D$  +242° (c 1.0, pyridine); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  2.12 (OCOCH<sub>3</sub>), 2.78 (NCH<sub>3</sub>), and 5.35 (>CHOCO), one proton doublet at 3.77 (C-2 H), and one proton multiplet at 3.23 (C-16 H);  $\nu^{KBr}_{max}$  1739 (s), 1613 (m), and 1244  $cm^{-1}$  (s).

*Anal.* Calcd for  $C_{22}H_{26}N_2O_4$ : C, 72.1; H, 7.15; N, 7.65. Found: C, 72.1; H, 6.96; N, 7.81.

In a similar experiment crystalline ajmalidine afforded the same O-acetate as colorless crystals, mp 218–219°.

**Oxidation of (–)-Galanthamine (16) to Narwedine (17).** A mixture of 1.00 g of 16, 10.5 ml of dimethyl sulfoxide, and 6.98 ml of acetic anhydride was stirred at room temperature for 18 hr. The solution was poured into 200 ml of ice-water and made alkaline with concentrated ammonium hydroxide. The mixture was extracted with dichloromethane and the extract was washed with water, dried over magnesium sulfate, and concentrated. Trituration of the residual yellow gum with ether and filtration gave 0.38 g (38%) of 17 as a yellow solid, mp 167–180° dec. Recrystallization from acetone gave 0.20 g of colorless crystals, mp 184–188°; lit.<sup>11</sup> mp 187–190°.

**Oxidation of Testosterone (18) to 4-Androstene-3,17-dione (19).**  
**A. With DMSO and Acetic Anhydride.** To a solution of 1.15 g of 18 in 12 ml of dry dimethyl sulfoxide was added 8 ml of acetic anhydride. The solution was stirred for 13 hr at room temperature and poured onto 125 g of ice. The mixture was made basic with 10 *N* sodium hydroxide, and the resulting precipitate was removed by filtration and washed thoroughly with water to give 1.10 g of white crystals. Recrystallization from ether gave 0.70 g (60%) of 19 as white crystals, mp 160–162°. Concentration of the mother liquors gave 0.25 g of crystals which were partitioned on a column of 640 g of Celite diatomaceous earth (stationary phase: 2-methoxy-ethanol saturated with heptane). The column was developed with heptane and the fraction which was collected at 3.8–5.8 hold-back

volumes (HBV) gave, on evaporation, 0.090 g (8%) of 19, mp 168–170°; lit.<sup>12</sup> mp 170°.

The fraction collected at 1.0–1.5 HBV was concentrated and the solid was recrystallized from petroleum ether (bp 30–60°) to give 0.117 g (8%) of 17 $\beta$ -[(methylthio)methoxy]-4-androsten-3-one (20) as colorless needles, mp 123–124°; lit.<sup>13</sup> mp 128–129°;  $[\alpha]^{25}_D$  +113° (c 1.1, CHCl<sub>3</sub>); pmr (CDCl<sub>3</sub>) singlets at  $\delta$  0.82 (CH<sub>3</sub>), 1.20 (CH<sub>2</sub>), 2.12 (SCH<sub>3</sub>), 4.60 (OCH<sub>2</sub>S), 5.70 (>C=C(CO)H);  $\nu^{KBr}_{max}$  1675 (s), 1626 (m), 1075 (s), and 1062  $cm^{-1}$  (s).

*Anal.* Calcd for  $C_{21}H_{28}O_2S$ : C, 72.4; H, 9.26; S, 9.20. Found: C, 71.9; H, 9.37; S, 9.07.

**B. With DMSO, Phosphoric Acid, Pyridine, and Ethoxyacetylene.** To a chilled mixture of 4.0 ml of dry dimethyl sulfoxide, 0.98 g (0.010 mole) of crystalline phosphoric acid, 0.577 g (0.0020 mole) of 18, and 0.95 ml (0.012 mole) of dry pyridine was added 1.0 ml of redistilled ethoxyacetylene. The mixture was allowed to warm to room temperature and stand at room temperature for 23 hr. The mixture was poured into 25 ml of ice-water and ten drops of acetic acid was added. The mixture was extracted with four 25-ml portions of dichloromethane; the combined extracts were washed with two 25-ml portions of water, dried over magnesium sulfate, and concentrated to a gum. Ether was added several times, and the solvent was removed *in vacuo* after each addition. Ether and heptane were added, and the solvent was evaporated to give 0.5 g of off-white crystals. Tlc on silica gel [solvent: cyclohexane-ethyl acetate (7:3)] showed the presence of three components: ca. 25% 4-androstene-3,17-dione, ca. 70% testosterone, and ca. 5% of a fast moving component [probably 17 $\beta$ -(methylthiomethoxy)-4-androsten-3-one]; the infrared spectrum showed a ketone band at 1747  $cm^{-1}$ . No testosterone O-acetate was present as determined by tlc comparison with an authentic sample.

**17 $\beta$ -(Methylthiomethoxy)-4-androsten-3-one (20).** To a mixture of 11.5 g (0.040 mole) of testosterone, 35 ml of dimethyl sulfoxide, and 40 ml of acetic anhydride was added 40 ml of glacial acetic acid. The mixture was chilled briefly and then allowed to stand at room temperature for 6 days. The solution was poured onto 500 g of ice and, after standing for 2 hr, was made basic with concentrated ammonium hydroxide. A gummy solid separated, and the liquid was decanted. The gummy solid was triturated with methanol and filtered to give 9.2 g of colorless crystals. Recrystallization from hot methanol gave 6.9 g (49%) of 20 as colorless crystals, mp 126–127°. Recrystallization from methanol afforded 5.35 g (38%) of colorless crystals, mp 127–128°; lit.<sup>13</sup> mp 128–129°.

**Oxidation of Hydrocortisone 21-Acetate (21) to Cortisone 21-Acetate (22).** A mixture of 0.404 g (0.0010 mole) of 21, 3 ml of dry dimethyl sulfoxide, and 2 ml of acetic anhydride was allowed to stand at room temperature for 56 hr. The mixture was poured into a mixture of 50 g of ice and 10 ml of water, and the resulting gummy precipitate was triturated while the pH of the mixture was adjusted to 7 by addition of concentrated ammonium hydroxide. Filtration gave 0.400 g of white crystals. Recrystallization from acetone gave 0.15 g (37%) of 22, mp 237–239°;  $[\alpha]^{25}_D$  +236° (c 0.63, CHCl<sub>3</sub>); lit.<sup>14</sup> mp 239–241°.

*Anal.* Calcd for  $C_{23}H_{36}O_6$ : C, 68.6; H, 7.51. Found: C, 69.0; H, 7.45.

In a similar run with 0.606 g (0.0015 mole) of 21 carried out for 92 hr, 0.57 g (94%) of product was obtained. Recrystallization from acetone-petroleum ether (bp 30–60°) afforded 0.31 g (53%) of 22 as colorless crystals, mp 236–239°.

**Oxidation of 11 $\alpha$ -Hydroxyprogesterone (23) to 11-Ketoprogesterone (24).** A mixture of 0.330 g of 23, 3 ml of dry dimethyl sulfoxide, and 2 ml of acetic anhydride was allowed to stand at room temperature for 25 hr. The solution was poured onto a mixture of 20 g of ice and 10 ml of water, made basic with concentrated ammonium hydroxide, and diluted with 25 ml of water. The mixture was extracted with chloroform, and the extracts were dried over magnesium sulfate and concentrated to give 300 mg of a gum. This material was chromatographed on a column of 440 g of Celite diatomaceous earth (stationary phase: methanol saturated with heptane) with a hold-back volume (HBV) of 600 ml, using heptane saturated with methanol as solvent. The fraction collected from 6.0–7.6 HBV was concentrated under reduced pressure to yield 0.100 g (30%) of 24 as a colorless glass. Crystallization from acetone-petroleum ether (bp 30–60°) gave 0.044 g (13%) of 24 as colorless crystals, mp 171–172°; lit.<sup>15</sup> mp 172–175°;  $\nu^{KBr}_{max}$  1709 (s), 1667 (s), and 1613  $cm^{-1}$  (m).

The fraction collected at 2.77–4.1 HBV was concentrated to give 0.220 g (56%) of methylthiomethoxy derivative 25 as a pale yellow gum which could not be induced to crystallize; pmr (CDCl<sub>3</sub>) singlets at  $\delta$  0.72 (CH<sub>3</sub>), 1.35 (CH<sub>2</sub>), 2.15 and 2.23 (COCH<sub>3</sub>, SCH<sub>3</sub>), 4.72

(OCH<sub>2</sub>S), 5.77 (>C=C(CO)H);  $\nu_{\text{max}}^{\text{KBr}}$  1709 (s), 1667 (s), 1613 (m), and 1042 cm<sup>-1</sup> (s).

**Oxidation of *p*-Nitrobenzyl Alcohol to *p*-Nitrobenzaldehyde.** A mixture of 1.53 g of *p*-nitrobenzyl alcohol, 30 ml of dry dimethyl sulfoxide, and 10 ml of acetic anhydride was allowed to stand at room temperature for 20 hr. The solution was poured onto 75 g of ice and allowed to stand for 1 hr. The chilled mixture was made basic with cold 10 *N* sodium hydroxide and extracted with ether. The ether extract was washed with water, dried over magnesium sulfate, and concentrated. The residue was triturated with ether and filtered, and the precipitate was recrystallized from ether to give 0.47 g (31%) of *p*-nitrobenzaldehyde as pale yellow crystals, mp 102–103° (infrared spectrum identical with an authentic sample).

The mother liquors were combined and concentrated to give 0.95 g of crystals which were recrystallized from ether to yield 0.55 g of crystals. The pmr spectrum (CDCl<sub>3</sub>) showed the latter crystals were a mixture composed of two-thirds *p*-nitrobenzaldehyde and one-third *p*-nitrobenzyl alcohol *O*-acetate: singlets at  $\delta$  2.13 (C(=O)CH<sub>3</sub>), 5.20 (CH<sub>2</sub>O), and 10.1 (CHO) with intensities of 1.5:1:1.

**Oxidation of Ethanol-<sup>18</sup>O with DMSO, Phosphoric Acid, and DCC.** To a mixture of 4.09 g (0.020 mole) of DCC and 5 ml of dry DMSO under nitrogen was added 0.300 g of crystalline phosphoric acid. The mixture became warm and was cooled. After standing for 15 min, 0.39 ml (0.0067 mole) of ethanol (containing 1.9% <sup>18</sup>O) was added. The temperature was kept below 20° by cooling and, after stirring for 1.33 hr, 10 ml of dry dichloromethane was added, and the mixture was filtered. The solid was washed with 200 ml of dichloromethane, two 20-ml portions of dry acetone, and finally with ethanol and water to give, after drying, 1.83 g of *N,N'*-dicyclohexylurea, mp 228–229°. Analysis by mass spectral measurements for <sup>18</sup>O content showed a maximum of 0.3% <sup>18</sup>O. In a similar run the solid which precipitated during the reaction was removed by filtration and washed with dichloromethane and ethanol. The solid was extracted with 250 ml of hot acetone, and the acetone extract was chilled and filtered to give 0.30 g of *N,N'*-dicyclohexylurea, mp 231–232°. Mass spectral analysis showed a maximum of 0.26% <sup>18</sup>O.

**Benzhydryl-<sup>18</sup>O.** A mixture of 4.04 g (0.020 mole) of benzhydryl chloride, 25 ml of dry acetone, and 5.0 ml of water labeled with 10% <sup>18</sup>O was allowed to stand at room temperature for 7 days. The solution was concentrated and filtered to give 3.3 g of colorless crystals. These crystals were washed with 10 ml of ethanol, and the ethanol wash was diluted with water. The resulting crystals were removed by filtration. The filtrate was concentrated, chilled, and filtered to give colorless crystals which were recrystallized from petroleum ether (bp 60–90°) to yield 0.53 g of benzhydryl as white needles, mp 64–65°. Mass spectral analysis showed the benzhydryl to contain 4.8% <sup>18</sup>O.

**Oxidation of Benzhydryl-<sup>18</sup>O with DMSO, Phosphoric Acid, and DCC.** A mixture of 0.184 g (0.001 mole) of benzhydryl-<sup>18</sup>O (4.8% <sup>18</sup>O), 0.613 g (0.003 mole) of DCC, 0.050 g of phosphoric acid, and 1 ml of DMSO was allowed to stand at room temperature for 16 hr.

The mixture was diluted with 8 ml of dry ether and filtered to remove solid A. To the filtrate was added 5 ml of water and several drops of acetic acid. After standing 6 hr, the mixture was filtered, and the solid was washed with ether. The ether was separated from the aqueous layer of the filtrate, and the aqueous layer was extracted with ether. The combined ether extracts were dried over magnesium sulfate and concentrated. The residue was extracted with petroleum ether (bp 60–90°) and the petroleum ether extract was concentrated to a gum. Mass spectral analysis of the crude benzophenone showed the presence of 2.0% <sup>18</sup>O (42% of the original label).

Solid A was washed with ether and with water to yield 0.39 g of white crystals. Recrystallization from acetone gave 0.31 g (0.00138 mole) of *N,N'*-dicyclohexylurea, mp 227°; no <sup>18</sup>O above natural abundance was found by mass spectral analysis.

**1,3-Dicyclohexyl-2-*p*-nitrobenzylpseudourea (40).** To a solution of 7.66 g (0.050 mole) of *p*-nitrobenzyl alcohol and 10.2 g (0.050 mole) of DCC in 150 ml of acetone was added 10 mg of anhydrous cupric chloride. The mixture was stirred at room temperature for 70 hr, and the solvent was then removed. The oil was dissolved in 30 ml of petroleum ether (bp 30–60°) and 30 ml of acetone and 1.0 g of *p*-nitrobenzyl alcohol and 10 mg of cupric chloride were added. After 70 hr the solvent was removed and a solution of the residual oil in ether was filtered through neutral alumina (Woelm, activity I). The first 250 ml of filtrate was concentrated to a pale yellow oil which crystallized on chilling [12.2 g (66%), mp 48–52°]. A portion (8.6 g) was recrystallized from petroleum ether (bp 30–60°) to give 7.1 g (38%) of 40 as nearly colorless crystals, mp 55–57°.

*Anal.* Calcd for C<sub>20</sub>H<sub>32</sub>N<sub>2</sub>O<sub>3</sub>: C, 66.8; H, 8.13; N, 11.7. Found: C, 66.3; H, 8.32; N, 11.9.

**Reaction of 1,3-Dicyclohexyl-2-*p*-nitrobenzylpseudourea (40) with DMSO and Phosphoric Acid.** A mixture of 3.61 g (0.010 mole) of 40, 0.40 g of crystalline phosphoric acid, and 12 ml of dry dimethyl sulfoxide was stirred at room temperature for 18 hr. The mixture was poured onto 50 g of ice and allowed to stand. The mixture was made basic with 10 *N* sodium hydroxide and extracted with ether. The ether extracts were concentrated, and the residue was diluted with water and extracted with petroleum ether (bp 30–60°). Concentration of the extract gave a pale yellow oil which crystallized. Chilling and filtering gave 2.2 g (61%) of starting material, mp 48–50°.

**Acknowledgment.** We wish to express our thanks to Mr. L. M. Brancone and staff for elemental analyses, Mr. W. Fulmor and staff for infrared, pmr, and ultraviolet spectral determinations, Mr. T. E. Mead and Mrs. R. H. Barritt (Research Service Department, Stamford Laboratories) for mass spectral determinations, Dr. P. Kohlbrenner and staff for the large-scale oxidation of yohimbine, and Mr. C. Pidacks and staff for partition chromatography.

# Studies on the Reaction between Peroxydisulfate Ions and Aromatic Amines. The Boyland-Sims Oxidation

E. J. Behrman

Contribution from the Department of Biochemistry, The Ohio State University, Columbus, Ohio 43210. Received January 9, 1967

**Abstract:** Aromatic amines and persulfate ions react in aqueous base to give a 45–55% yield of *o*-aminoaryl sulfate, ammonia, and a polymeric material known as humic acid. The reaction is first order in neutral amine and initially first order in persulfate ion. The effect of substituents on the rate of the reaction, the activation parameters, and the lack of effect of a radical trap suggest a nucleophilic displacement by the amine nitrogen on peroxide oxygen to give the corresponding arylhydroxylamine O-sulfonate. This postulated intermediate may then rearrange to the *o*-aminoaryl sulfate or be oxidized by persulfate to humic acid and ammonia.

The reaction between aromatic amines and peroxydisulfate (persulfate, peroxydisulfate) ions in aqueous base to form *o*-aminoaryl sulfates was first reported in 1953.<sup>1</sup> The preparative aspects of this reaction were explored in a series of further papers which established the scope of the reaction.<sup>2–4</sup> The reaction might appropriately be named the Boyland-Sims oxidation. Primary, secondary, and tertiary aromatic amines are all successfully converted to the *o*-sulfate esters, although the yields of isolated material are frequently poor. The range is generally between 10 and 40%. If both *ortho* positions are blocked, *para* substitution takes place. Otherwise, *ortho* substitution is exclusive except for the case of the persulfate oxidation of anthranilic acid<sup>5</sup> in which a small proportion of the *para* isomer was detected. Much starting material is generally recoverable, even though an excess of persulfate is used. The reaction mixtures are highly colored<sup>2,6</sup> and a number of products in addition to the sulfate esters have been reported. Azo and azoxy compounds have been isolated<sup>4</sup> and a substituted quinone imine has been found as a product of the oxidation of 2-naphthylamine.<sup>1</sup> The formation of insoluble, brown, amorphous material, frequently in substantial amounts, has been noted in a number of these oxidations.<sup>1,3,4</sup> The scope of the reaction has been extended to include indoles and aminopyrimidines.<sup>7,8</sup> The results of a preliminary mechanistic study of this reaction<sup>9</sup> suggested that it proceeds *via* a nucleophilic displacement on peroxide oxygen<sup>10</sup> rather than by a radical mechanism, and that it is, therefore, closely allied to the Elbs persulfate oxidation of phenols<sup>11</sup> with the notable exception of the orientation of the sulfate group. This investigation was undertaken with the hope of defining those

differences between the phenol and the amine oxidations which for the latter case lead to preferential *ortho* substitution.

## Materials and Methods

2-Amino-3-hydroxypyridine and 2-amino-3-pyridyl hydrogen sulfate were prepared by the persulfate oxidation of 2-aminopyridine according to Boyland and Sims.<sup>4</sup> 2,2'-Azopyridine and 2-nitropyridine were prepared according to Kirpal and Böhm.<sup>12</sup> 2-Amino-3,5-dideuteriopyridine was prepared by heating 20 g of D<sub>2</sub>O, 4.7 g of 2-aminopyridine, and 2.45 g of sulfuric acid in a sealed tube at 180° (refluxing 2-octanol) for 90 hr. At the end of this period, the tube was cooled, the contents removed, and the volatile material removed *in vacuo*. An additional 20 g of D<sub>2</sub>O was then added and the heating repeated. A third run was then completed following which the reaction mixture was made basic with sodium hydroxide and extracted continuously with ether. The ether was removed and the material crystallized from *n*-hexane-ether. The yield was 2.7 g. The calculated isotopic purity is 99.8%. Examination of the nmr spectrum of the product in D<sub>2</sub>O showed no trace of the multiplet attributable to the 3 and 5 protons centered at  $\tau$  3.4, and the collapse of the 4-proton triplet to a singlet at  $\tau$  2.4. Other amines were obtained from Eastman or Aldrich and were either redistilled or recrystallized before use. Inorganic compounds were reagent grade and were used without further purification.

Kinetic runs were carried out in a water bath held to within 0.1° of the indicated temperature. The kinetics of the reactions were followed by measurement of persulfate concentration as a function of time using the iodometric method of Kolthoff and Carr<sup>13</sup> with the modification that the reaction aliquots were quenched in acetic acid which was consequently present during the 15-min incubation. The blank value was 0.1 ml of 0.01 *M* thiosulfate. Kinetics were run under pseudo-first-order conditions with the amine present in at least tenfold excess. The formation of 2-amino-3-hydroxypyridine was followed by assay with the Folin phenol reagent, essentially according to the method already described.<sup>11</sup> Hydrolysis of the sulfate ester was complete within 5 min at 100° in 3 *N* HCl. The blue color produced by the reduction of the Folin phenol reagent

was measured in a Klett-Summerson photoelectric colorimeter using the 660-m $\mu$  filter. 2-Aminopyridine does not interfere. 2-Amino-3-hydroxypyridine (0.1  $\mu$ mole) gave a Klett reading of 90. Beer's law was obeyed up to at least a Klett reading of 400. 2-Amino-3-hydroxypyridine is stable to heating in acid but is rapidly destroyed under these conditions in the presence of persulfate.

The formation of 2-amino-5-nitrophenol from *p*-nitroaniline was measured similarly. The formation of *o*-aminophenol from aniline was measured by use of the Folin uric acid reagent.<sup>14</sup> Ammonia was determined by direct Nesslerization.

## Results

2-Aminopyridine was chosen as the model amine for these studies because of the ease of product determination.

**1. Yield and Stoichiometry.** Yield of material capable of reducing the Folin phenol reagent was examined as a function of the ratio of the reactants, of temperature, and of hydroxyl ion concentration. These results are summarized in Table I. All reactions were run for a sufficiently long time to consume at least 99% of the smaller component. The yield appears to be independent of temperature, but dependent on both the hydroxyl ion concentration and the ratio of the reactants.

**Table I.** Yield of 2-Amino-3-hydroxypyridine from the Reaction of Persulfate and 2-Aminopyridine

[2-AP] <sup>a</sup>	[S <sub>2</sub> O <sub>8</sub> <sup>2-</sup> ]	Ratio	[KOH]	Temp, °C	Yield, <sup>b</sup> %

0.10	0.01	10	0.09	40	46
0.10	0.01	10	0.018	40	50

<sup>a</sup> 2-AP is 2-aminopyridine. <sup>b</sup> Yield determinations are the averages of two runs.

The ultraviolet spectra of ether extracts of reaction mixtures were examined for the presence of 2-nitrosopyridine, 2-nitropyridine, 2,2'-azopyridine, and 2,2'-azoxypyridine. None of these materials was detected. Paper chromatography of reaction mixtures following acid hydrolysis revealed only one Folin-positive spot corresponding to 2-amino-3-hydroxypyridine, although a number of other unidentified ultraviolet-absorbing spots were present.

**2. Order in Persulfate.** At an amine:persulfate ratio of 10, the disappearance of persulfate followed apparent first-order kinetics for about 75% of the reaction, when the kinetics were examined as plots of the logarithm of persulfate concentrations *vs.* time; a negative deviation was evident thereafter. A typical plot is shown in Figure 1. If, however, successive *k*

**Figure 1.** Rate plot for the oxidation of 2-aminopyridine by persulfate. Conditions were: 0.450 *N* KOH, 0.5 *M* 2-aminopyridine, 0.0501 *M* K<sub>2</sub>S<sub>2</sub>O<sub>8</sub>, 40.0°. The solid line represents the experimental findings; the dotted line is straight.

values are computed, a steady drift to more negative values is evident. The drift during the first half of the reaction is less than 5%.

**3. Order in Amine.** Table II shows that the reaction is likewise first order in amine. We may thus write the rate law,  $v = k[S_2O_8^{2-}][ArNH_2]$ , at least for the major part of the reaction.

**Table II.** Order in 2-Aminopyridine<sup>a</sup>

[2-AP]	[S <sub>2</sub> O <sub>8</sub> <sup>2-</sup> ]	<i>k</i> , l./mole min
0.040	0.0038	0.0403
0.100	0.010	0.0392
0.1062	0.010	(0.0402)
0.200	0.024	0.0404
0.300	0.0295	(0.0397)
0.400	0.030	0.0405

<sup>a</sup> General conditions: 0.475 *M* KOH, 40.0°. 2-AP is 2-aminopyridine. *k* values were calculated by measurement of the pseudo-first-order rate constant during the first half-time of the reaction and division of this constant by 2-aminopyridine concentration. The values given are the averages of duplicate determinations with the exception of the values marked with parentheses, which are the result of single runs. The average *k* value is 0.0401.

**4. pH Dependency.** The variation of rate with pH is shown in Figure 2 and demonstrates that it is the unprotonated amine which is the reactive species. 2-Aminopyridine has a *pK<sub>a</sub>* of 6.9. The ionic strength was constant within this series of experiments.

**5. Salt Effects.** Table III shows that there is a general and positive salt effect of rather small magnitude, as expected for a reaction between an ion and an uncharged molecule.

**6. Activation Parameters.** The variation of the rate constant with temperature is given in Table IV. The derived activation parameters are as follows: *E<sub>a</sub>* = 15.7 ± 0.3 kcal/mole;  $\Delta S^\ddagger$  = -25.5 ± 1 eu. These values are of the magnitude expected for nucleophilic displacement on peroxide oxygen.<sup>10</sup>

(14) E. J. Behrman and M. N. D. Goswami, *Anal. Chem.*, **36**, 2189 (1964).

Figure 2. The effect of pH on the rate of oxidation of 2-aminopyridine by persulfate. General conditions were: 0.200 *M* 2-aminopyridine, 0.020 *M* persulfate, 40.0°. Buffers were added such that the ionic strength increment was equal to 0.475. The specific pH values and additions were: pH 13.7, KOH; pH 11.1, phosphate; pH 9.7, carbonate; pH 8.1, phosphate; pH 7.3, phosphate; pH 6.3, phosphate; pH 5.0, acetate; pH 4.0, acetate.

**7. Effect of Radical Traps.** Allyl acetate, an effective sulfate radical trap,<sup>15</sup> had no effect on the rate of disappearance of persulfate in the presence of 2-aminopyridine at pH 7. The final yield of 2-amino-3-hydroxypyridine was likewise unaffected. The rate of

Aniline	0.0302	C	40.0	0.0764	2.53
Aniline	0.0121	C	40.0	0.0298	2.47
Aniline	0.0121	D	40.0	0.0297	2.46
Aniline	0.0302	C	30.0	0.0399	1.32
<i>p</i> -Toluidine	0.0300	C	30.0	0.101	3.36

<sup>a</sup> Solvents: A, 0.475 *M* KOH in 24% 2-propanol; B, 0.04 *M* phosphate buffer, pH 7.0 in 24% 2-propanol; C, 0.04 *M* phosphate buffer, pH 7.0 in water; D, 0.1 *M* KOH in water. <sup>b</sup> These values have been corrected for the rate of oxidation of 2-propanol by subtracting 0.00018 from the pseudo-first-order rate constants.

that the reaction is accelerated by electron-releasing substituents. A Hammett plot of these data suggests a  $\rho$  value in the vicinity of  $-1.3$ . This may be compared with the value of  $-1.86$  reported for the reaction of aromatic amines with peroxyacetic acid,<sup>16</sup> and of  $-1.58$  for the reaction of nitrosobenzenes with peroxyacetic acid.<sup>17</sup> The rate of oxidation of aniline is decreased by about a factor of two in 24% 2-propanol as compared with water as solvent. In accordance with the evidence that the reactive species of 2-aminopyridine is the unprotonated amine, the rate of oxidation of aniline ( $pK_a = 4.6$ ) is the same at pH 7 and in 0.1 *M* KOH. *p*-Nitroaniline is oxidized more rapidly in 0.475 *M* KOH than at pH 7, but this is perhaps attributable to ionization to the anion.<sup>18</sup>

**9. Site of Attack.** Since aromatic amines are ambident nucleophiles, either attack at carbon or attack at nitrogen followed by rearrangement is *a priori* conceivable. Table VI compares the rates of oxidation of three sets of aromatic amines in which one *ortho* position is blocked and a common substituent is placed either *meta* to the amino group (*para* to the final position of the sulfate group) or *para* to the amino group (*meta* to the final position of the sulfate group). One isomer will react with persulfate faster on the hypothesis of rate-limiting electrophilic attack at nitrogen, the other on the assumption of rate-limiting electrophilic attack at carbon. For each set, the order of reactivity is that to be expected on the basis of rate-limiting attack at nitrogen, as shown by the values of the  $\sigma$  constants.

**10. Rate of Oxidation of 2-Amino-3,5-dideuterio-pyridine.** The rate of oxidation of this material by persulfate was identical with that of the undeuterated material. The yield of product at hydroxyl ion concentrations from 0.1 to 3 *M* as measured by the quantity of Folin-reactive material present following acid hydrolysis was likewise unaffected by deuteration.

**11. Formation of Ammonia from 2-Aminopyridine and 2-Amino-3-hydroxypyridine.** Considerable quantities of ammonia are produced during the oxidation of 2-aminopyridine by persulfate. At 2-aminopyridine: persulfate ratios between 100 and 10, in 0.9 *M* KOH

II runs were conducted at 40.0°. The initial amine:persulfate was 10 in all cases. Values for the  $\sigma$  constants are from J. "Physical Organic Chemistry," 2nd ed, McGraw-Hill Book Co., New York, N. Y., 1962, pp 87-90.

°, the molar ratio between ammonia produced and sulfate added is between 0.34 and 0.21. Thus only 30% of the persulfate added in these experiments, where the yield of 2-amino-3-pyridyl hydrogen sulfate is in the 45-55% range (see Table I), is consumed in reactions resulting in deamination. 2-Aminotrioxypyridine reacts with persulfate at least 1000 times faster than 2-aminopyridine to give a quantitative yield of ammonia and oxidation products (see below). o-Aminophenol likewise gives a quantitative yield of ammonia, while aniline, like 2-aminopyridine, gives a yield of about 30%. 2-Amino-3-pyridyl hydrogen sulfate reacts with persulfate, but only at a rate about one-half that of 2-aminopyridine.

**Formation of Material with the Properties of Synthetic Humic Acid.** When an alkaline mixture of aniline and persulfate is acidified, a dark polymeric material precipitates. The ultraviolet spectrum in alkaline solution shows no peaks at wavelengths longer than 220 m $\mu$ . The infrared spectrum is shown in Figure 3. Oxidation of o-aminophenol by persulfate under alkaline conditions produced a similar material whose infrared spectrum is shown for comparison in Figure 3. The spectra, although not identical, are closely similar. The oxidation of o-aminophenol by persulfate in alkali was described in 1925 by <sup>19</sup> The product is a member of the class of materials known as synthetic humic acid. In quantitative yields, the oxidation of 1 mole of aniline by 0.1 mole of persulfate in 1 l. of 0.5 M KOH gave an isolated yield of 1 g of this polymer. These are conditions which give a 50-55% yield of o-aminoaryl sulfate so that the isolated yield of sulfate ester and polymer amounts to roughly 75-80% of starting material.

## Discussion

The evidence suggests rate-limiting electrophilic attack of the persulfate ion on nitrogen of the neutral amine. W. Eller, *Ann.*, **442**, 173 (1925).

Figure 3. Infrared spectra of humic acids isolated from the persulfate oxidation of aniline (upper curve) and of o-aminophenol (lower curve). The spectra were taken in mineral oil mulls using a Perkin-Elmer Model 237B.

followed by rearrangement to the o-aminoaryl sulfate. Attack at nitrogen rather than at carbon is consistent with work in other systems.<sup>16, 17, 20-23</sup> Haberfield and Paul have recently demonstrated the existence of an N-chloro intermediate in the chlorination of N-methylaniline.<sup>24</sup>

The effect of substituents in the persulfate-aromatic amine reaction argues strongly for electrophilic attack at nitrogen. Initial attack at nitrogen also provides the rationale for the preferential *ortho* orientation. The absence of significant radical involvement is shown by the first-order dependence on both amine and persulfate and by the lack of effect of radical traps on either the rate of disappearance of persulfate or the yield of o-aminoaryl sulfate. The points of difficulty are the nature of the initial product resulting from attack of the peroxide on nitrogen and the fate of those molecules which do not appear as o-aminoaryl sulfate. If the attack were initially at nitrogen, a reasonable intermediate would be the arylhydroxylamine-O-sulfonate.

Salts of phenylhydroxylamine-O-sulfonate have been prepared by Boyland and Nery.<sup>25</sup> These authors report that phenylhydroxylamine O-sulfonate rearranges to o-aminophenyl sulfate on standing at room temperature in 2 N HCl. The paper states that salts of the various hydroxylaminesulfonic acids "are unchanged in 2% aqueous sodium hydrogen carbonate or 2 N ammonia after 16 hr at room temperature in the dark..." and that "In hot 2 N sodium hydroxide they give complex mixtures containing o- and p-aminophenol, aniline, azoxybenzene, and unidentified products." Our attempts to demonstrate the presence of alkali-labile material in aniline-persulfate reactions run at neutrality were unsuccessful. However, Professor Boyland has informed me that although the N-acyl derivatives are stable, phenylhydroxylamine-O-sulfonic acid itself is unstable in solution at all pH values, that the potassium salt shows signs of decom-

position in the solid state at 0° after a few days, and that considerable rearrangement occurs during chromatography of the compound in neutral solvent systems.<sup>26</sup> Although we cannot say how the rate of rearrangement of the arylhydroxylamine-O-sulfonates to the *o*-aminoaryl sulfates varies as a function of pH, it appears that the O-sulfonates are at least not unreasonable intermediates in the reaction between aromatic amines and persulfate ions. Boyland and Nery also report that phenylhydroxylaminesulfonic acids (both O- and N-substituted compounds are discussed) reduce ammoniacal silver nitrate and Fehling's solution. Aniline does not reduce either solution. Phenylhydroxylamine-O-sulfonate is thus a better reducing agent than the parent amine. This is reasonable since the hydroxylamines are members of the class of nucleophiles which exhibit an enhanced degree of nucleophilic reactivity which has been termed the  $\alpha$  effect by Edwards and Pearson.<sup>27</sup> This aspect of their expected behavior is consistent with their role as intermediates in the persulfate oxidation of aromatic amines and with the low yields of *o*-sulfates obtainable in the reaction. The postulated intermediate is more readily oxidized than the starting material. The yield of *o*-aminoaryl sulfate falls in strong alkali, a fact perhaps attributable to even more ready attack by persulfate on the dianion of the arylhydroxylamine-O-sulfonate. We may write a general scheme for the course of the reaction

where X may be the arylhydroxylamine-O-sulfonate. On the steady-state assumption, the ratio of the rate of formation of *o*-aminoaryl sulfate to the rate of formation of further oxidation products will be equal to  $k_2/k_3[\text{persulfate}]$ . This expression is then consistent with the dependence of the yield on the persulfate: amine ratio and also explains the deviation from first-order dependence on persulfate concentration.

(27) J. O. Edwards and R. G. Pearson, *J. Am. Chem. Soc.*, **84**, 16 (1962).

The major product of the reaction other than the *o*-aminoaryl sulfate is a polymer known as synthetic humic acid. Materials of this class were reported as products of the alkaline persulfate oxidation of dihydric phenols and aminophenols by Eller.<sup>19,28</sup> Even monohydric phenols are oxidized to humic acids with persulfate: phenol ratios of 2 to 4.<sup>28b</sup> These are conditions under which the phenol *p*-sulfate (the normal Elbs product) is formed in very low yield.<sup>11</sup> Ziechmann and Scholz<sup>29</sup> and Elofson<sup>30</sup> have reported spectroscopic characteristics of humic acids from a variety of sources which are thought to arise through condensation of hydroxyquinones.<sup>31</sup> A substituted naphthoquinone imine of this oxidation level has been identified as a product of the persulfate oxidation of 2-naphthylamine.<sup>1</sup> Characterization of humic acids is difficult and we have not undertaken this task here. Recent reviews are available.<sup>32,33</sup> It suffices for our purposes to have shown the close similarity between the polymeric material obtained from the oxidation of *o*-aminophenol, known to be oxidized to a humic acid by persulfate,<sup>19</sup> and that obtained from aniline. A corresponding product is presumably obtained from 2-aminopyridine, but due to the ring nitrogen, it is soluble in acid and we have not isolated it.

The humic acid polymers should be distinguished from polymers of the aniline black-emeraldine type which result from homolytic coupling of aromatic amines in acid solution.<sup>34</sup>

## Ozonolysis. Steric and Stereochemical Effects in the Olefin

R. W. Murray,<sup>1a</sup> R. D. Youssefeyeh,<sup>1a,b</sup> and Paul R. Story<sup>1c</sup>

Contribution from the Bell Telephone Laboratories, Inc., Murray Hill, New Jersey, and the Department of Chemistry, The University of Georgia, Athens, Georgia.

Received November 21, 1966

**Abstract:** Ozonolysis of a series of *cis* and *trans* olefins indicates that the ozonide *cis:trans* ratio produced in both normal ozonides and cross-ozonides is a function of both olefin stereochemistry and steric effects in the olefin. Isolation of an epoxide in which the olefin stereochemistry has been preserved has been observed in the case of one *trans* olefin. The mechanistic consequences of these results are discussed.

It has now been amply demonstrated<sup>2-9</sup> that olefins can give both *cis* and *trans* ozonides. Of greater significance to the mechanism of ozonolysis are a few observations which indicate that the ozonide *cis:trans* ratio obtained can be a function of olefin stereochemistry. A different ozonide *cis:trans* ratio is obtained from the stereoisomers of di-*t*-butylethylene,<sup>2</sup> 1,4-dibromo-2,3-dimethylbutene-2,<sup>3</sup> methyl *p*-methoxycinnamate,<sup>6</sup> and a number of simple alkenes.<sup>7-9</sup>

Also of considerable importance to the study of the mechanism of ozonolysis are the reports by several groups<sup>5,8-10</sup> that unsymmetrical olefins give, in addition to the expected unsymmetrical ozonide *cis-trans* pair, two symmetrical ozonide *cis-trans* pairs derived from the cleavage of the olefin unsaturation. We have recently shown that a combination of these two important pieces of information, that is, the formation of cross-ozonides and the observation of ozonide *cis-trans* pairs, can be used to provide results which raise serious questions about the general validity of the Criegee mechanism of ozonolysis.<sup>11</sup> Specifically, it was shown that the ozonide *cis:trans* ratios observed in cross-ozonides are also dependent upon olefin geometry.<sup>12</sup> In these cases the intervention of an intramolecular stereoselective pathway, such as was considered to explain similar results in the normal ozonide cases,<sup>8,9</sup> is not possible. These results have led us to propose a new path to ozonide formation in which the molozonide assumes the role of a true intermediate in an exchange reaction with aldehydes, and, thus, exerts an influence on the ozonide *cis:trans* ratios produced.<sup>13</sup>

The observation that both ozonide and cross-ozonide *cis:trans* ratios can be dependent on olefin geometry provides a powerful new probe for studying the mechanism of ozonolysis. Effective use of this

probe requires that the ozonide stereoisomer designations be made on an unequivocal basis, however. Such an assignment has recently become available<sup>14</sup> and is based on the fact that the *trans* isomer of a symmetrical ozonide must consist of a *dl* pair and, hence, be amenable to complete or partial resolution.

The establishment of a comprehensive mechanism of ozonolysis on a sound basis requires that a number of variables be studied in a systematic manner. We report here the results of such a study in which the major emphasis is on the effect of olefin steric factor and olefin stereochemistry.

## Discussion of Results

We consider first the normal<sup>15</sup> ozonides produced upon ozonolysis of a series of olefins. In the *cis* series there is a clear dependence of the ozonide *cis:trans* ratios on the substituent size in the olefin as shown in Table I. A similar, although less-pronounced, effect

Table I. Normal Ozonide Stereoisomers from *cis* Olefins

Olefins	<i>cis</i> , %	<i>trans</i> , %	Total yield <sup>a</sup> of ozonides, %
	67	33	84
	66	34	85
	54	46	81
	53	47	81
	49	51	86
	42	58	91
	41	59	72
	39	61	48

<sup>a</sup> It should be noted that for unsymmetrical olefins this figure includes the yield of cross-ozonide.

(14) R. W. Murray, R. D. Youssefeyeh, and P. R. Story, *ibid.*, **88**, 3655 (1966).

(15) The term normal ozonide is here used to describe the parent ozonide obtained upon ozonolysis of an olefin. For a symmetrical olefin this is a symmetrical ozonide. For an unsymmetrical olefin it is the unsymmetrical ozonide. The two symmetrical ozonides obtained in the latter case are here referred to as cross-ozonides.

is seen in the *trans* series for olefins below, and including, diisopropylethylene in steric requirements (Table II). In the *cis* series this effect is in the form

Table II. Normal Ozonide Stereoisomers from *trans* Olefins

Olefins	<i>cis</i> , %	<i>trans</i> , %	Total yield <sup>a</sup> of ozonides, %

	38	62	56
	38	62	36

<sup>a</sup> It should be noted that for unsymmetrical olefins this figure includes the yields of cross-ozonide. <sup>b</sup> Yield of one or both cross-ozonides could not be determined.

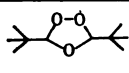

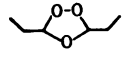

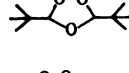

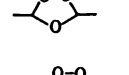

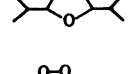

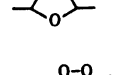

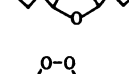

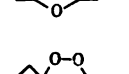

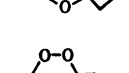

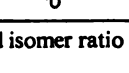

of a higher per cent *cis* ozonide accompanying higher steric requirements in the olefin. The same effect is noticed in the *trans* series for olefins below diisopropylethylene. The remaining two members of the *trans* series, both of which contain a *t*-butyl group, do not follow this trend but instead give a much higher per cent *trans* ozonide. The results reported earlier by Schröder also fit well into these two series. For *cis*-di-*t*-butylethylene Schröder obtained a 70:30 *cis:trans* ratio, placing it at the top of the *cis* series, consistent with its higher steric requirements. Likewise, for *trans*-di-*t*-butylethylene he reported obtaining 100% *trans* ozonide, which places this result in the group at the top of the *trans* series. Apparently, the presence of the *t*-butyl group in the *trans* olefins introduces a new factor which disrupts the trend in the ozonide *cis:trans* ratios. Our observations with two members of this group indicate that these same olefins are also most prone to give olefin-ozone adducts which undergo rearrangements. One of these rearrangements, that which gives *t*-butyl formate, involves migration of the *t*-butyl group. These processes are undoubtedly competing with ozonide formation and are probably responsible for the change in trend in the ozonide *cis:trans* ratios as well as the lower yields obtained in these cases.

The difference in the steric effect between the *cis* and *trans* series is seen to diminish with size of substituent until the diethylethylene case (hexene-3) is reached where the ozonide isomer distribution is the same for both series at 53:47 (*c:t*). In fact with all of the olefins below hexene-3 in steric requirements both olefin series

give approximately the same ozonide isomer distribution, and the steric effect on this ratio within either series is less pronounced than for those olefins having greater steric requirements than hexene-3.

Examination of the ozonide *cis:trans* ratios obtained in the *cross*-ozonides reveals a similar trend to that observed in the *normal* ozonides, although fewer examples are available to support this general observation (Tables III and IV). The effect is quite clear in the

Table III. Cross-Ozonide Stereoisomers from *trans* Olefins

<sup>a</sup> Yield and isomer ratio could not be obtained but ozonides were produced.

*cis* series where the larger of the two cross-ozonides obtained for each olefin is quite sensitive to the steric factor in the olefin. Thus, in the series, *cis*-4,4-dimethylpentene-2, *cis*-4-methylpentene-2, and *cis*-pentene-2 the *cis:trans* ratios in the cross-ozonides di-*t*-butylozonide, diisopropylozonide, and diethylozonide were 74:26, 66:34, and 56:44 (*c:t*), respectively. A similar trend is perhaps discernible in the *trans* series, but this conclusion must be regarded as tentative. One point is clear, however. As reported earlier,<sup>12</sup> the *cis:trans* ratios for cross-ozonides are dependent on olefin geometry for a number of olefins. To us this observation is inconsistent with the Criegee zwitterion mechanism, in which the zwitterion precursor to ozonide should give the same ozonide *cis:trans* ratios for both olefin stereoisomers in both normal and cross-ozonides. In considering alternatives to this mechanism<sup>13</sup> we have considered several possible pathways as being in competition, with the Criegee zwitterion pathway retained as a possible contributing pathway.

<sup>a</sup> Yield and isomer ratio could not be obtained but ozonides were produced.

An additional observation can be made relative to the *cis:trans* cross-ozonide ratios obtained in the *cis* series. In many cases this ratio for the larger of the two cross-ozonides obtained is almost identical with the ratio obtained from the symmetrical *cis* olefin which would give the same ozonide. In the *cis*-4,4-dimethylpentene-2 case, for example, the di-*t*-butyl-ozonide obtained has a 74:26 (*c:t*) ratio while Schröder<sup>2</sup> reported a 70:30 (*c:t*) ratio for the same ozonide from *cis*-di-*t*-butylethylene. Likewise, *cis*-4-methylpentene-2 gives a 66:34 (*c:t*) ratio for the diisopropyl-ozonide, which is exactly the same ratio obtained from the symmetrical olefin, *cis*-2,5-dimethylhexene-3. A similar situation exists for the hexene-3 ozonides from *cis*-pentene-2 and *cis*-hexene-3 where the ratios are 56:44 and 53:47 (*c:t*), respectively. In the case of *cis*-*t*-butylethylene, on the other hand, the di-*t*-butyl-ozonide produced has the remarkably high *cis:trans* ratio of 82:18. This result surely argues against a pure zwitterion mechanism for cross-ozonide formation. In fact, the cross-ozonides from the *cis* olefins taken as a whole suggest an intermediate for their production which is quite sensitive to steric factors in the olefin and, like the normal ozonides, the correlation is that higher steric requirements leads to a higher per cent *cis* ozonide being produced.

We have proposed a mechanism which we believe to be consistent with these observations<sup>13</sup> (Scheme I). According to this proposal an olefin can give either a molozonide 2 or a  $\sigma$  complex 3 with either of these adducts perhaps, but not necessarily, preceded by a

$\pi$  complex 1. The percentage of each pathway taken will depend on the stereochemistry and steric factors present in the olefin. In general *cis* olefins are more likely than *trans* to take the  $\sigma$ -complex pathway, and those which are badly sterically hindered proceed almost exclusively *via* this pathway, at least in producing normal ozonides. The molozonide pathway has several alternatives available to it, one of which is to cleave to give the Criegee zwitterion 4 and a carbonyl compound 5. The other alternative gives to the molozonide the role of a true intermediate which is visualized as cleaving to a zwitterionic form 6 either prior to or assisted by the approach of an aldehyde molecule, with which it will undergo an aldehyde exchange reaction. This latter reaction gives either normal ozonide or cross-ozonide, depending upon the nature of the aldehyde. The direction of cleavage of 2 shown here is contrary to that usually given<sup>16</sup> in which the single oxygen carries the positive charge. It is our contention that a structure in which the positive charge can be delocalized over two oxygen atoms will be more stable. The adduct between the opened molozonide and the aldehyde is a transitory intermediate 7 which can exist in four possible conformations 7a-d. Two of these conformers are precursors to a *cis* ozonide and two to a *trans* ozonide.<sup>13</sup> This process for the case of *cis*-4-methylpentene-2 and isobutyraldehyde is depicted in Scheme I. Examination of scale molecular models for this case reveals that one of these conformations is preferred (7c), since it contains only H-H non-bonded repulsions. Since this conformation leads to *cis* ozonide, the ozonide formed in this aldehyde interchange is expected to have a higher per cent *cis* configuration as observed. A similar analysis starting with the *trans* isomer is depicted in Scheme II. Here a consideration of the possible conformations of the molozonide-aldehyde adduct shows no over-all preference for *cis* or *trans* ozonide precursor. Again, the experimental results are in keeping with this analysis; e.g., see the cases of the diisopropyl ozonide formed from *trans*-4-methylpentene-2 and the hexene-3 ozonide formed from *trans*-pentene 2. It should be remembered that in all cases the observed *cis:trans* ratio is believed to be the net result of contributions from several pathways. In the cases just discussed, for example, these detailed pathways are seen as the dominant contributions to the observed ratio with other pathways making smaller contributions.

Another observation which seems to be generally true is that the *cis* olefins always give a higher yield of ozonide than the *trans*. This is true both for normal ozonides and cross-ozonides. Similar results with respect to normal ozonides have been reported by Schröder,<sup>2</sup> Greenwood and Haske,<sup>7</sup> and Lorenz and Parks.<sup>8</sup> We have also observed an increase in yields of free aldehyde in the *trans* series, as well as the production of acids which sometimes complicated isolation of the ozonides by glpc. Where the steric effect is especially pronounced as, for example, in *trans*-2,2-dimethylhexene-3, sufficient quantities of both ester and epoxide are produced to permit their isolation. The gas chromatograms also indicated that traces of these materials were formed in some of the other

(16) R. Criegee in "Peroxide Reaction Mechanisms," J. O. Edwards, Ed., Interscience Publishers, Inc., New York, N. Y., 1962, p 32.

*trans* olefins. All of these observations seem to be consistent with the mechanistic scheme described above. That is, ozonolysis of a *trans* olefin is expected to involve a greater percentage of the pathways originating with molozonide. These pathways involve the polar intermediates 4 and 6, either of which can undergo rearrangements to give the acids and esters. These pathways might also be expected to give lower yields of ozonides since they involve a greater degree of separation of olefin fragments. The *cis* isomers, on the other hand, are more likely than the *trans* to proceed via the pathway involving the  $\sigma$  complex 3, which can proceed directly to normal ozonide without involving the molozonide or separation of olefin fragments. Important to this view is the reported<sup>17</sup> absence of a molozonide upon ozonolysis of *cis*-di-*t*-butylethylene, whereas the *trans* isomer gives a molozonide which is stable at  $-75^\circ$ . Greenwood<sup>7</sup> has suggested that *cis* olefins in general may also give molozonides which are

much less stable than those from the *trans* isomers. The conclusion was based in part upon the production of a white solid upon ozonolysis of *cis*-hexene-3, and the subsequent explosive decomposition of this material upon warm-up. While Greenwood's interpretation seems reasonable, it may be that the unstable species which is found in the *cis* case is not a molozonide at all, but a different species, perhaps the  $\sigma$  complex or something related to it. Besides explaining the higher yields the  $\sigma$  complex pathway may be the reason for the observed greater retention of configuration for hindered *cis* olefins.

The basic reason for *cis* olefins being more likely to involve the  $\sigma$  complex than the *trans* is perhaps seen from a critical examination of the steric requirements for its formation with the aid of scale models. The formation of the complex is depicted as involving approach of the ozone molecule so that the plane of the three oxygen atoms is perpendicular to the plane containing the olefinic carbon atoms. The complex itself is seen as having one end oxygen of the ozone

(17) R. Criegee and G. Schröder, *Chem. Ber.*, **93**, 689 (1960).

molecule above the olefinic carbon plane and the other end oxygen below this plane. It is this assembly which it is proposed can proceed stereospecifically and intramolecularly to ozonide. Formation of such an assembly and its subsequent internal rearrangement are both more difficult in a *trans* olefin than in the *cis* isomer.

Isolation of the epoxide in the case of *trans*-*t*-butyl-ethylethylene provides further valuable information which may be highly pertinent to the mechanistic scheme described above. While the production of epoxides upon ozonolysis has been reported previously,<sup>18</sup> this appears to be the first case of isolation of an epoxide where the olefin is capable of giving both *cis* and *trans* epoxides. The epoxide obtained from this *trans* olefin has the *trans* structure as evidenced by the fact that it is identical with that obtained by peracid epoxidation of the same olefin. This could be a very significant result in that it may provide evidence for an initial olefin-ozone adduct in which the olefin

stereochemistry is preserved, and which is capable of proceeding to products, in this case the epoxide. Such an initial adduct could be the  $\pi$  complex proposed earlier by Bailey<sup>18</sup> or the  $\sigma$  complex proposed by us.<sup>13</sup> This is the type of complex which we have proposed may proceed stereospecifically to ozonide particularly in the case of hindered *cis* olefins. Further work on the mechanism of production of epoxides and their stereochemistry is in progress.

The results described here indicate a definite influence of olefin stereochemistry and steric factors on the ozonide *cis:trans* ratios produced. Olefin stereochemistry also exerts a strong influence on the total yield of ozonide as well as on the possibility of producing such minor products as acids, esters, and epoxides. We have attempted to describe a mechanistic scheme to account for all of these observations and, while we feel that the scheme proposed does provide a cohesive framework for the ozonolysis reaction, it has some obvious shortcomings. Further refinement of the scheme must await the results of studies in progress on the effects of solvent, concentration, and temperature.

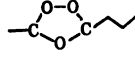

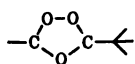

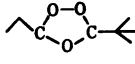

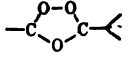

### Experimental Section

The nmr spectra were determined on a Varian A-60 high-resolution nmr spectrometer. Elemental analyses are by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. 11377. The glpc analyses were carried out on an Aerograph Model A-700 gas chromatograph using a 10 ft, 10% cyanosilicone column.

**Ozonolyses.** A Welsbach Model T-23 ozonator was used as a source of ozone. The ozonolyses were carried out at ca.  $-70^\circ$  using a 1 *M* solution of the olefin in pentane. Ozonolysis was continued to 75% of the theoretical ozone required. The reaction mixtures were analyzed by glpc using an Aerograph Model 471 digital integrator to obtain quantitative data. The assignment of *cis* and *trans* structures to the ozonide geometric isomers was made on the basis of glpc, infrared, and nmr data and the correlation of these data with the unequivocal assignment based on partial resolution

<sup>a</sup> Abbreviations used are: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. <sup>b</sup> Corresponds to the weight ratio for the total peaks indicated in the bracket.

of the *trans-dl* pair for diisopropylazonide.<sup>14</sup> The *cis* isomer has the longest glpc retention time. In the infrared spectra the *trans* isomer is characterized by a band at *ca.* 1320 cm<sup>-1</sup> which is absent in the *cis* isomer. Likewise the *cis* isomers have a band at *ca.* 830 cm<sup>-1</sup> which is missing in the *trans* spectra. Examination of the data in Table III will reveal a consistent correlation in the nmr spectra as well. For a symmetrical ozonide the methine hydrogens are always at lower field in the *cis* isomer. In the case of an unsymmetrical ozonide at least one of these protons will be at lower field in the *cis* isomer.

The *cis:trans* ratios reported are the result of several integrations of the glpc peak areas and have a maximum variation of  $\pm 0.5\%$ . Control experiments demonstrated that the glpc conditions used do not affect the ozonide *cis:trans* ratios. A summary of yields, analytical data, and nmr data is given in Table V.

In the case of *trans*-2,2-dimethylhexene-3 sufficient quantities of two additional materials were produced to permit their isolation. The first of these has a relatively low glpc retention time (6.2 min

at 70°). Its nmr spectrum consists of just two singlets at 2.21 and 8.58 with an integrated area ratio of 1:9. Of the two most likely structures for this material, the aldehyde, pivalaldehyde, is eliminated on the basis of nmr spectra since the aldehyde has two sharp singlets at 0.52 and 8.87. This material is therefore assigned the other possible structure containing highly deshielded protons, namely *t*-butyl formate. The second new material, isolated in 4% yield, has nmr and infrared spectra identical with those for authentic *trans*-2,2-dimethylhexene-3 epoxide obtained by the epoxidation of *trans*-2,2-dimethylhexene-3 using *m*-chloroperbenzoic acid.

an intermediate,  $R_2S^+(NH)Cl$ , which is structurally analogous to sulfoxonium ions and which would solvolyze to the sulfone imine.

The sulfoxide could also conceivably have been formed by hydrolysis of the reactive sulfimine by adventitious moisture, although not by alcoholysis.<sup>4</sup> No alternate scheme for the formation of sulfone imine is apparent. The sulfone diimine is hydrolytically inert (see later), and the possibility that the sulfone imine could have been formed by amination of sulfoxide was also ruled out. The sulfoxide is nearly inert to chloramine under the reaction conditions, and it is inconceivable that the observed high sulfone imine:sulfoxide ratio (ca. 6:1) would have occurred if sulfoxide amination were the mode of sulfone imine formation.

It is clear from these results why hydroxylic solvents are to be avoided in the synthesis if possible. Displacement on chlorine likely occurs to some extent in acetonitrile; however, ammonolysis of the S-chloro species would lead to the same product as if direct displacement on nitrogen had occurred.<sup>10</sup>

### Proof of Structure

The reported nmr spectra of the diimines formed from dimethyl and diethyl sulfide<sup>1,2</sup> clearly establish that the alkyl groups remain intact and exist in magnetically equivalent environments. The structural problem is reduced by these facts to determining whether the sulfimine intermediate is aminated by chloramine in the second stage of the synthesis on nitrogen or on sulfur. Amination on sulfur leads to structure I and tetrahedral coordination of sulfur, while N-amination yields II or III and trigonal sulfur. The dipolar form II would probably be much less stable than its tautomeric isomer III. Both tautomers have equivalent skeletal symmetry that is distinctly different from the tetrahedral diimine structure, I. Thus, the vibrational spectrum ought to allow one to distinguish between these two forms.

Here we report the Raman spectra of the dimethyl, diethyl, and methyl dodecyl derivatives of the chloramine-dialkyl sulfide reaction product. A vibrational

(10) H. Takai, I. Watanabe, and T. Makaiyama, *Bull. Chem. Soc. Japan*, **38**, 1989 (1965).

analysis and band assignment for the dimethyl derivative is consistent with  $C_{2v}$  symmetry, and strongly supports I as the correct structure of the group. Additional evidence has been obtained from infrared spectra and from the chemical properties of the compounds. The latter evidence is considered later at appropriate points in the description of these properties.

**Dimethyl Sulfone Diimine. A. Spectroscopic Evidence.** The Raman spectrum of a concentrated aqueous solution of the dimethyl sulfone diimine is exhibited in Figure 1 along with comparison spectra of liquid dimethyl sulfide and unsymmetrical dimethylhydrazine (u-DMH). Qualitative inspection of the spectra indicates the preservation of bands arising from the  $(CH_3)_2S$  functional group and the completely different pattern for the hydrazine spectrum. In particular, we note the absence of an intense, polarized band in the 700–900- $cm^{-1}$  range which can be assigned as the N–N stretching region for a hydrazine structure (808  $cm^{-1}$  (Raman), 802  $cm^{-1}$  (infrared) for u-DMH). In addition, we can find no evidence for bands associated with the  $NH_2$  group. In u-DMH, the  $\delta(NH_2)$  deformation occurs at 1606  $cm^{-1}$  with  $2\delta(NH_2)$  at 3207  $cm^{-1}$ , probably in Fermi resonance with  $\nu_{sym}(NH)$  at 3332  $cm^{-1}$ . These  $NH_2$  motions persist as discernible features in 25% aqueous solutions of u-DMH. In chloroform solution, both the Raman and the infrared spectra of I exhibit a single band at 3311  $cm^{-1}$ , indicating degeneracy of the in-phase and out-of-phase NH stretch consistent with  $R_2S(NH)_2$  and not  $R_2S-N-NH_2$ .

Table I summarizes the Raman data obtained on the aqueous sample of dimethyl sulfone diimine. Frequency assignments are based on comparison with the Raman spectra of dimethyl sulfide  $((CH_3)_2S)$ <sup>11</sup> and dimethyl sulfone  $((CH_3)_2SO_2)$ ,<sup>12</sup> and the infrared data on sulfamide  $((NH_2)_2SO_2)$ .<sup>13</sup> For clarity, bands associated with the sulfonyl group or interaction of  $SO_2$  with other modes have been omitted from the table.

The dimethyl sulfide group appears to be unperturbed by formation of the diimine structure though the methyl hydrogen stretches do appear to be sensitive to changes in sulfur bonding. Again, note the absence of bands associated with the  $NH_2$  group:  $NH_2$  rocking modes at 720 and 1131  $cm^{-1}$ , the  $NH_2$  scissors at 1557

cm<sup>-1</sup>, and the NH<sub>2</sub> stretch triplet at 3112, 3223, and 3323 cm<sup>-1</sup> in the sulfamide.

The Raman spectrum of crystalline (CH<sub>3</sub>)<sub>2</sub>S(NH)<sub>2</sub> and of a 50% aqueous solution of dimethyl sulfone imine ((CH<sub>3</sub>)<sub>2</sub>S(O)NH) are presented in Figure 2. Table II summarizes the observed positions of the vibrations and proposed assignments. The similarity in the skeletal vibrations for these two molecules is immediately

apparent. Not only is the visual display (pattern) of the spectra of these two tetrahedral molecules quite similar, but there are, in addition, many close coincidences in the actual positions of bands arising from similar modes of vibration. The replacement of NH by O transforms the weak ν<sub>asym</sub>(SN) at 962 cm<sup>-1</sup> into the more intense ν(SO) at 1031 cm<sup>-1</sup> (1050 cm<sup>-1</sup> in aqueous media).

Figure 2. Raman spectra of crystalline dimethyl sulfone diimine and aqueous dimethyl sulfone imine.

**B. Vibrational Assignment.** The dimethyl sulfide reaction product can be analyzed as a pseudo-pentatomic molecule if we neglect all hydrogen motions. This is a reasonable approximation since we expect only very weak coupling between the light hydrogen atom vibrations and motions of the heavier skeletal atoms. For each of the pentatomic models we expect nine fundamental skeletal vibrations with all modes observable

Figure 3. Raman spectra of diethyl sulfide, crystalline diethyl sulfone diimine, and methyl dodecyl sulfone diimine. Gain: A, 100; B, 200; C, 500; D, 40.

in the Raman. Four of these fundamentals should arise primarily from stretching motions and five from angle deformations.

The diimine structure I has  $C_{2v}$  symmetry. Its vibrational representation is  $4A_1 + A_2 + 2B_1 + 2B_2$ . There should be one inactive infrared fundamental ( $A_2$ , a torsional mode) and four polarized Raman lines. Two of the latter should be intense and arise from C-S and N-S stretching motions.

The hydrazine structure III (or II) has  $C_s$  molecular symmetry. With a vibrational representation of  $6A' + 3A''$ , all modes should be active in both the infrared and Raman. However, the six  $A'$  modes should be polarized in the Raman and three of these should be strong lines related to C-S, S-N, and N-N stretching motions.

Since hydrogen deformations are weak scatterers in the Raman, we can expect all strong bands observed below  $1100\text{ cm}^{-1}$  to arise from skeletal motions. The Raman spectrum of an aqueous solution of the alkyl sulfide reaction product exhibits only two strong polarized lines in the skeletal stretching region and no evidence for a third, strong, polarized band associated with the N-N stretch. We associate the paired couplets 679, 741, and 947, 975  $\text{cm}^{-1}$  with the symmetric and asymmetric motions of  $(\text{CH}_2)_x\text{S}$  and  $(\text{NH})_x\text{S}$ , respectively, and note the absence of strong interaction between the two pairs of vibrators. The remaining five bands we assign to the predicted five deformation modes. The proposed band assignments for the skeletal motions are summarized in Table III. The assignment of  $\nu_7$  and  $\nu_8$  to SNH motions is based on the increase in apparent intensity of the respective Raman bands upon crystallization and the formation of intermolecular hydrogen bonds (see below). All assignments are consistent with those of ref 12 and 13.

**Dialkyl Sulfone Diimines.** In addition to the methyl derivative, we have also examined the Raman spectra of the diethyl and the methyl dodecyl derivatives. Representative data are listed in Table IV with typical spectra illustrated in Figure 3. Spectral assignments are complicated by the presence of rotational isomers<sup>14</sup>

<sup>a</sup> Aqueous solution

which generate multiple strong Raman bands in the  $600\text{--}700\text{ cm}^{-1}$  region. Diethyl sulfide data have been included to aid in the comparison. Again we note the persistence of the characteristic vibrations of the dialkyl sulfide group and the absence of strong perturbation by amination. These data are also quite consistent with the diimine structure proposed for the dimethyl sulfide reaction product. The characteristic positions for Raman bands associated with the  $\text{S}(\text{NH})_x$  structural unit in dialkyl sulfone diimines are summarized in Table V. The variation in characteristic frequency appears to be consistent with the effects of hydrogen bonding on each vibrational mode and the presence of water in the sample. The S-N asymmetric stretch and the SNH deformation would be expected to be more prominent in the infrared, and may be of some diagnostic value.

### Properties

**Thermal Stability.** The thermal stability of dimethyl and diethyl sulfone diimines is sufficient to allow them to be analyzed by gas chromatography at  $150^\circ$ , with partial decomposition at the inlet. After 16 hr at  $100^\circ$ , neat methyl dodecyl sulfone diimine is largely decomposed, to the products shown.

Ammonia, azide ( $\text{N}_3^-$ ), and thiocyanate ( $\text{SCN}^-$ ) were also detected.

As with amine oxides,<sup>15</sup> the thermal stability of the sulfone diimines is greatly enhanced in hydroxylic solvents. An aqueous solution of methyl dodecyl sulfone diimine underwent less than 10% decomposition under the same conditions which completely decomposed the neat sample (above).

**Hydrolysis and Reduction Reactions.** The extraordinary resistance of sulfone diimines toward acid- or base-catalyzed hydrolysis<sup>2</sup> has been confirmed. Dimethyl sulfone diimine was recovered unchanged after 67 hr at  $100^\circ$  in water; no hydrolysis products were detectable either by infrared spectra or gas chromatographic analysis. Similar results were obtained after 1.5 hr at  $100^\circ$  in 2 *N* sodium hydroxide.

The cleavage of the C-S bond in sulfone diimines by aqueous hydrochloric acid to form alkyl chlorides and sulfonic acids has been reported,<sup>2</sup> and we obtained

<sup>a</sup> Calculated from potentiometric titration curves following the method of A. Albert and E. P. Serjeant, "Ionization Constants of Acids and Bases," John Wiley and Sons, Inc., New York, N. Y., 1962, p 33. <sup>b</sup> Calculated following the method of Albert and Serjeant, p 38. <sup>c</sup> S. K. Hall and E. A. Robinson, *Can. J. Chem.*, **42**, 1113 (1964). <sup>d</sup> P. Nylen, *Z. Anorg. Allgem. Chem.*, **246**, 227 (1941).

identical results. Unexpectedly, the reaction took a completely different course in aqueous hydrochloric acid containing potassium iodide (2.4 N HCl, 6 N KI). A few per cent cleavage to alkyl halides was again observed, but the major products were the dialkyl sulfide and iodine. Sulfoxides are also reduced to sulfides by iodide in acidic solution.<sup>16</sup>

The reluctance of the group to undergo acid- or base-catalyzed hydrolysis to sulfone imines or sulfones constituted supporting evidence for structure I. The related sulfone imines are also resistant to hydrolysis, whereas structures II or III, being N-substituted sulfinimines, should resemble the parent sulfinimines in being readily hydrolyzable.

Methyl dodecyl sulfone diimine reacted exothermically with massive quantities of hydrogen-bearing W-2

Raney nickel in alcohol. Methyl dodecyl sulfide (18%) and dodecane (10%) were isolated.

**Basicity and Metal Complexing.** The pK<sub>A</sub> data in Table VI show that the sulfone diimines are weakly basic molecules. They are about 2.5 pK units more basic than sulfone imines.

The pK<sub>A</sub> data also constitute evidence which favors I as the correct structure of the group. Structure III can be viewed as a modified hydrazine, in which a partial negative charge resides on one nitrogen.

(16) D. Landini, F. Montanari, H. Hogeveen, and G. Maccagnani, *Tetrahedron Letters*, 2691 (1964).

Figure 4. Solubility diagram of dimethyl sulfone diimine in water.

This negative charge would be expected to increase the basicity of III over that of hydrazine itself, so that the predicted  $pK_A$  of the conjugate acid of III should be  $>8.5$ . The much lower values observed rule against structure III. It is impossible to predict exactly what the basicity of I should be, but if the same difference exists between its basicity and that of  $NH_2^-$  as exists between that of sulfones and  $OH^-$ , a value in the neighborhood of 6 for the  $pK_A$  of its conjugate acid would be anticipated.<sup>17</sup> The original structure proposal,<sup>1</sup>  $R_2S^+-NH-NH^-$ , is not stabilized by semipolar bonds and, in having an amide ion insulated from the sulfur by the  $-NH-$  group, should be considerably more basic than was observed (compare  $R_2N^+NH_2$  with a  $pK_A > 15$ ).

The metal complexing ability of the sulfone diimine group with metal salts from vanadium to zinc in the first long row of the periodic table (in convenient oxidation states) was screened in a qualitative fashion. Obvious complexing occurred only with V(IV), Cr(III), Fe(III), and Cu(II). The complexing ability of the sulfone diimine thus parallels that of aliphatic amine oxides in general, in line with the close similarity in basicity of the two groups (Table VI).

With silver nitrate, each of the sulfone diimines formed an insoluble grayish precipitate which was accompanied by a sharp decrease in the pH of the solution to 2–3.<sup>18</sup> It thus appears that actual liberation of mineral acids occurs in aqueous solution through reaction with silver ion, although potentiometric titration with base revealed no clean-cut stoichiometry. No such pH effect was noted with any other metal ion. Formation of the precipitate was reversible: addition of nitric acid redissolved it. Also, it was not formed from silver acetate in glacial acetic acid. The latter system constituted a convenient qualitative test for chloride in the presence of sulfone diimines.

(17) The  $pK_A$  of  $H-OH$  (15) is lowered to  $-12$  in  $R_2S^+(O)-OH$ , a difference of 27  $pK$  units. Taking 33 as the  $pK_A$  of  $NH_3$ ,  $R_2S^+(O)NH_2$  should have a value of 6 if the same difference were observed (the actual value is 3), and  $R_2S(NH)-NH_2$  would not be expected to be terribly different. This crude line of reasoning only shows that the observed values are in a reasonable range.

(18) The formation of a precipitate with silver ion was previously reported,<sup>1</sup> but not the pH effect.

**Polarity and Hydrogen Bonding.** The sulfone diimine group is a polar functional group, as indicated by the high water solubility of the dialkyl derivatives. Figure 4 describes the water solubility of dimethyl sulfone diimine. Methyl dodecyl sulfone diimine is likewise water soluble, while methyl dodecyl sulfone is by contrast totally insoluble.

The vibrational spectral data suggest that the sulfone diimine group readily engages in hydrogen bonding. Spectrally, hydrogen-bond formation is manifested in intensity changes, band broadening, and frequency shifts.<sup>19</sup> For dimethyl sulfone diimine  $\nu_1$ ,  $\nu_2$ , and  $\nu$  (NH) are shifted from 415, 933, and 3311  $cm^{-1}$  in relatively inert chloroform to 436, 947, and 3250  $cm^{-1}$  in aqueous solution. This corresponds to an increase in the resistance to deformation of a bending mode and an effective elongation of the NH bond upon hydrogen bond formation. Dimethyl sulfone imine exhibits similar spectral effects in a comparison of chloroform and aqueous solution spectra:  $\nu(SN)$  shifts from 982 to 989  $cm^{-1}$ ,  $\nu(SO)$  from 1020 to 1050  $cm^{-1}$ , and  $\nu(NH)$  from 3340 to 3274  $cm^{-1}$ .

Hydrogen-bond formation is more pronounced in the crystalline state, as indicated by the larger shift of the NH stretching frequencies summarized in Table VII. Extensive hydrogen bonding is evident in crystal-

Table VII. NH Stretching Bands,  $cm^{-1}$

Compound	Crystal	Aqueous	$CHCl_3$
$(CH_3)_2S(NH)_2$	3190	3250	3311
$(CH_3)_2S(O)NH$	3191	3274	3340
$(C_6H_5)_2S(NH)_2$	3227	3290	...
$(CH_3)(C_{12}H_{25})S(NH)_2$	3178 3222	3304	...

line dimethyl sulfone diimine:  $\nu_2$  and  $\nu_1$  are stronger and sharper bands and  $\nu_1$  is split into two components. The splitting is interpreted as arising from intermolecular interaction rather than local site symmetry effects since  $\nu_2$  is not split in the crystalline spectrum.<sup>21</sup>

Only one type of imine hydrogen is indicated in the solution and crystalline spectrum for the dimethyl derivative; thus we propose a general structural model of the form

(19) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman and Co., San Francisco, Calif., 1960.

(20) All aqueous NH stretching bands are broadened and their positions are less certain owing to variation in internuclear distance caused by hydrogen bonding.

(21) Preliminary X-ray diffraction studies<sup>22</sup> indicate each of the eight molecules in the unit cell is situated at a local site with  $C_2$  symmetry. Thus,  $\nu_1$  and  $\nu_2$  should be similarly affected if crystal site splitting is operative.

(22) N. Webb, these laboratories, personal communication.

present the spatial interaction with either water (aqueous) or diimine (crystal). This model also illustrates the dual nature of the diimines in accepting hydrogen-bonding hydrogens in interaction with other electrophilic atoms.

The shift of  $\nu(\text{NH})$  for crystalline diethyl sulfone diimine is  $35\text{ cm}^{-1}$  less than for the dimethyl derivative, indicating a weaker hydrogen bond. This probably results from van der Waals repulsion of the alkyl fragments leading to lattice packing problems. When one of the alkyl groups is replaced by a bulky long chain in the unsymmetrical methyl dodecyl derivative we observed two NH bands, indicating both a long and a short  $\text{NH}\cdots\text{N}$  bond.

If we assume a value of  $3350\text{ cm}^{-1}$  for free imine stretching frequency,<sup>23,24</sup> then the average shift of  $30\text{ cm}^{-1}$  allows us to estimate the crystalline hydrogen-bond strengths for these diimines as 2.5–3.0 kcal/mole for the  $\text{NH}\cdots\text{N}$  bond.<sup>19,25,26</sup> On the same basis, the interaction with water is probably of the order of 2.0–3.0 kcal/mole. Thus the solvation of the diimines is governed by the availability of 4–5 kcal/mole of diimine–water interaction energy.

## Discussion

In the synthesis of the sulfone diimines, all the available imines of sulfoxides<sup>4</sup> and sulfones have been used. It is, therefore, of interest to compare the results with each other and with the parent oxygen compounds.

The various imines may be conveniently divided into two classes: sulfoxide-like structures incorporating one semipolar bond, and sulfone-like structures in which two semipolar bonds are formed to the same heteroatom. Comparison of the sulfone diimines with the sulfimines reveals that the same fundamental relationship in properties which exist between sulfones and sulfoxides also exist between the two classes of imines. The thermal stability of the sulfone diimines clearly exceeds that of the sulfimines. For comparable decomposition, roughly  $100^\circ$  higher temperatures are required for the sulfone diimines. Also, the basicity of the sulfimines appears to exceed that of the sulfone diimines, as is the case with sulfoxides and sulfones (Table VI). While direct measurement of the basicity of sulfimines in aqueous solution is precluded by their hydrolytic instability, they are known to form an adduct with carbon dioxide in nonhydroxylic solvents,  $\text{R}_2\text{N}^+\text{HCO}_2^-$ ,<sup>27</sup> whereas the sulfone diimine group does not. A chloroform solution of the latter saturated with carbon dioxide shows the free  $\text{CO}_2$  infrared band, with no absorption corresponding to  $-\text{CO}_2^-$  or  $-\text{CO}_2\text{H}$ . On the other hand, the sulfimines are not sufficiently stable to prevent their liberation from their conjugate acids at least in part, by ammonia. The aqueous  $\text{pK}_\text{A}$  of the species  $\text{R}_2\text{S}^+-\text{NH}_2$  is therefore most likely in the range 8–10.

A higher frequency than the  $3311\text{ cm}^{-1}$  observed in  $\text{CHCl}_3$  is expected since self-association and/or interaction with the acidic proton of formic acid would tend to lower the free  $=\text{NH}$  frequency.

N. B. Colthup, *J. Opt. Soc. Am.*, **40**, 397 (1950), cites a range of  $3400\text{ cm}^{-1}$  for an imine NH.

R. Schroeder and E. R. Lippincott, *J. Phys. Chem.*, **61**, 921 (1957).

D. Nakamoto, M. Margoshes, and R. E. Rundle, *J. Am. Chem. Soc.*, **77**, 6480 (1955).

R. Appel and G. Büchler, *Ann.*, **684**, 112 (1965).

Examination of the presently known imines reveals a striking difference between the two classes, above, with regard to hydrolytic reactivity. It appears to be generally true that sulfoxide-like imines are readily hydrolyzable to the parent oxygen compounds, while sulfone-like imines are hydrolytically inert. The acid- or base-catalyzed hydrolysis of a sulfone imine or diimine has so far never been observed.<sup>28</sup> Examples of hydrolytically reactive sulfoxide-like imines include  $\text{R}_2\text{S}\rightarrow\text{NH}^+$  and  $\text{R}-\text{S}(\text{NH})\text{NH}_2$ .<sup>29</sup> Similarly reactive phosphorus imines which are "sulfoxide-like" in the above sense include  $\text{R}_2\text{P}\rightarrow\text{NH}^+$  and  $(\text{H}_2\text{N})_2\text{P}\rightarrow\text{NH}$ .<sup>31</sup>

Now let us consider the relationship between sulfoxides and sulfones, and their imine derivatives. It is apparent that the thermal stability of the imines is significantly lower than that of the oxygen compounds. Sulfimines decompose at room temperature and below, sulfoxides in the vicinity of  $150^\circ$  and higher. Sulfone diimines decompose rapidly at slightly over  $100^\circ$ , sulfones only at temperatures well over  $200^\circ$ .<sup>32</sup> The sulfone monoimine is more like the sulfone than the sulfone diimine in this respect.

Another fundamental distinction between the S–N and S–O compounds is the course which thermal decomposition takes. Both fragment to olefins, when  $\beta$  elimination is permitted by the structure. However, the S–N compounds (both sulfimines and sulfone diimines) yield the parent dialkyl sulfide as a major decomposition product whereas with sulfoxides and sulfones the dialkyl sulfide is a very minor product.<sup>33</sup> The possibility that the dialkyl sulfide is not a primary decomposition product but is formed by a secondary reaction between olefin and mercaptan cannot be rigorously excluded.

Another prominent difference between the oxygen and nitrogen analogs exists with regard to basicity and metal complexing. The figures in Table VI indicate the two sulfone imines to be 15–18 pK units more basic than the corresponding sulfone, a figure comparable to the difference between amide and hydroxide ion ( $\text{pK}_\text{A}$  of  $\text{NH}_3 \cong 33$ ,  $\text{pK}_\text{A}$  of  $\text{H}_2\text{O} \cong 15$ ). The cause for the large difference in each case stems from the difference in nuclear charge of nitrogen and oxygen.

It is evident from this work that the sulfur atom of sulfimines is appreciably more nucleophilic toward chloramine than is that of sulfoxides. Chloramine reacts preferentially with the sulfimine intermediate in the presence of high ammonia concentrations at temperatures below  $0^\circ$ . Sulfoxides, by contrast, compete

(28) Indirect hydrolysis of the monoimine by reaction with hydrogen peroxide or nitrous acid has been carried out [A. Schöberl and A. Wagner, "Methoden der Organischen Chemie (Houben-Weyl)," Vol. 9, Eugen Müller Ed., Georg Thieme Verlag, Stuttgart, 1955, p 220; F. Misani, T. W. Fair, and L. Reiner, *J. Am. Chem. Soc.*, **73**, 459 (1951)]. However, the monoimines have been recovered unchanged from refluxing 50% sodium hydroxide (J. S. Berry, private communication from these laboratories).

(29) This species is presumably formed as the initial sulfur-containing product of the hydrochloric acid cleavage of sulfone diimines. Hydrolytically reactive aromatic derivatives have also been reported [G. Kresse, C. Seyfried, and A. Trede, *Tetrahedron Letters*, 3933 (1965)].

(30) H. H. Sisler, A. Sarkis, H. S. Ahuja, R. J. Drago, and N. L. Smith, *J. Am. Chem. Soc.*, **81**, 2982 (1959); R. Appel and A. Hauss, *Chem. Ber.*, **93**, 405 (1960).

## Experimental Section

Melting point (capillary, Mel-Temp apparatus, uncorrected) and analytical data are listed in Table VIII. Elemental analyses were performed by our analytical department. Nmr data were determined with a Varian HA-100 spectrophotometer. The chemical shifts of S-methyl groups in various compounds are tabulated in Table IX. The spectra of the long-chain compounds included other features expected from the structure, namely a triplet for the  $-\text{CH}_2-$   $\alpha$  to the sulfur downfield from the S-methyl absorption, characteristic long-chain absorption at  $\tau$  8.75 and 9.15 (methylene protons and terminal methyl protons), plus broad absorption slightly downfield from most of the methylene protons attributable to the  $\beta$ -methylene group. Table X gives complete nmr data for diethyl sulfone diimine in various solvents.

Raman spectra were obtained on the Cary 81 Raman spectrophotometer using 4358-A mercury excitation and capillary cells (0.2-cc capacity). The instrument was calibrated with respect to argon, neon, and helium emission lines from low-pressure discharge lamps, and all strong Raman bands are believed accurate to  $\pm 2$  cm<sup>-1</sup>. The hygroscopic nature of the samples made it convenient to obtain spectra from aqueous solutions although crystalline and chloroform solution spectra were also obtained. All solutions were filtered through activated charcoal and 0.45- $\mu$  Millipore filters to minimize fluorescence and scattering from particulate matter. Polarization data were obtained in the conventional manner using Polaroid cylinders.

Good infrared spectra were difficult to obtain free from the interfering effects of absorbed moisture. The solution spectra reported were taken on a Perkin-Elmer 421 grating spectrometer.

Gas chromatography was carried out on a Model 700 F & M instrument, using a 10% Apiezon on polytetrafluoroethylene column. Partial decomposition of the dimethyl sulfone diimine in the inlet (kept <170°) prevented quantitative application of gc,

but a standard mixture of dimethyl sulfone, sulfone imine, and sulfone diimine approached the expected peak area ratios sample levels (several milligrams). Relative retention times: dimethyl sulfone, sulfoxide, sulfone imine, and sulfone diimine 1.0, 0.87, 1.53, and 1.90, respectively. At a column temperature 135° (0.25-in. columns, 50 cc of He/min), the sulfone had a retention time of ca. 3 min.

The reference sulfone imines were prepared from sulfone and hydrazoic acid by the method of Whitehead and Bentley.<sup>34</sup> Thin layer chromatography (tlc) was carried out on standard gel G plates, developed with methanol except where noted. The spots were visualized by spraying with 25% acid and charring.

**Dimethyl Sulfone Diimine.** In a 500-ml, three-necked flask equipped with a 10-mm diameter gas inlet tube, stirrer, an cold-finger condenser fitted with a drying tube were placed (0.10 mole) of dimethyl sulfide and 180 ml of acetonitrile (dry 4A molecular sieves). Chloramine-ammonia from a generator operating at 10 mmoles/min of Cl<sub>2</sub> and 10:1 NH<sub>3</sub>:Cl<sub>2</sub> ratio passed in at -15° for 1 hr (ca. 0.4 mole), and the flask placed in a -20° ice-salt bath and stirred overnight. The temperature in the morning. The reaction was filtered, the filtrate evaporated to dryness *in vacuo*, and the residue sublimed at 80–90° (0.1 mm). Yields varied from 12 to 39% of material which was largely diimine contaminated by sulfoxide and sulfone imine as determined by gas chromatography. The hygroscopic crystals could be purified by recrystallization from acetonitrile or resublimation attempts to improve this work-up procedure or scale up the reaction to 0.3 mole gave poorer yields.

**Diethyl Sulfone Diimine.** Diethyl sulfide (9.0 g, 0.10 mole) was aminated as described above for dimethyl sulfide. The filtrate evaporated, taken up in acetonitrile, and washed with 50% aqueous potassium carbonate until chloride free (see preparation of dodecyl homolog for description of test), the solvent evaporated and the residue distilled; bp 70° (0.1 mm). The distillate (51%) had a freezing temperature of 48°,<sup>1,2</sup> and was identical to that of Cogliano and Braude.<sup>35</sup> It could be gas chromatographed through the same column used for the dimethyl homolog.

**Methyl Dodecyl Sulfone Diimine.** In a 2-l. apparatus similar to that described above, but without the condenser, were placed (0.400 mole) of methyl dodecyl sulfide and 1300 ml of acetone (dried over 4A molecular sieves). Chloramine was passed into the flask at 0–5° during four 1-hr periods, at an average rate of 0.5 mole/hr. After each 1-hr period, the glass wool-ammonium chloride filter was replaced. The reaction was then stirred over 0° and filtered cold.

The filter cake was extracted thoroughly with 2-propanol, the bulk of the 2-propanol removed *in vacuo* using a rotary evaporator.<sup>36</sup> The residue was then redissolved in 2-propanol washed several times with 50% aqueous potassium carbonate a test sample of ca. 1 ml, dissolved in 3–5 ml of glacial acetic acid gave no precipitate with a few drops of aqueous 0.5% silver nitrate test reagent. The 2-propanol was again evaporated and the residue recrystallized from ethyl acetate or acetonitrile, yield 45%. Tlc indicated the once recrystallized product to be pure but contaminated with sulfone imine, sulfoxide, and a minor impurity with R<sub>f</sub> 0. Multiple recrystallizations reduced these impurities to a level not detectable on the chromatogram with a 1000- $\mu$ g (<0.5%). Work-up of the mother liquors from recrystallization of the main product yielded 11% recovered sulfide, plus 1% dodecene and 1% dodecanenitrile. Each was unambiguously identified by gas chromatography retention times on a polar nonpolar column, infrared spectra, and (in the case of the

(34) J. K. Whitehead and H. R. Bentley, *J. Chem. Soc.*, 1572 (1952).

(35) If this evaporation was omitted, it proved to be essentially impossible to wash the system free of chloride with the potassium carbonate.

the nmr spectrum. The sulfone diimine (Infracord, mull) showed infrared bands at 3.02 (m), 3.4 (s), 3.5 (s), 3.85 (m), 7.1 (m), 7.65 (m), 9.1 (s, broad), 9.5 (s), 9.75 (m), 10.15 (m), 10.45 (m), 10.85 (s), 13.1 (w), 13.45 (m), 13.55 (m), 13.9 (m), and  $14.2 \mu$  (w).

A similar preparation was carried out in molecular sieve dried 2-propanol. After stirring overnight, the reaction was filtered and the ammonium chloride precipitate washed with 2-propanol. The combined filtrate and washings were evaporated, taken up in 2-propanol, and worked up as described above; yield 44%.

Tlc of the crude 2-propanol reaction product after the carbonate washes showed four spots at  $R_f$  0, 0.48, 0.64, and 0.75, which corresponded to an unknown compound (possibly the sulfimine or its hydrochloride, or the hydrochloride of the sulfone diimine), the sulfone diimine, the sulfone imine and/or sulfoxide, and the sulfide, respectively. To determine the amounts of these quantitatively, the amination was repeated under identical conditions on 2.00 g of sulfide, and the entire reaction product chromatographed on a silica gel column ( $22 \times 280$  mm), eluting first with 2-propanol and then with 3A ethanol. The yield of recovered sulfide (free of dodecene) was 8%, the sulfone imine-sulfoxide fraction 7%, and the sulfone diimine fraction 64%. The nmr spectrum of the sulfone imine-sulfoxide fraction showed the two components to be present in ca. 5:1 ratio, from the relative intensities of the  $\text{S-CH}_3$  peaks at  $\tau$  7.05 and 7.46. A ratio of this magnitude was confirmed by tlc using a solvent system later found to resolve sulfoxide from sulfone imine (95:9:1:0.5 chloroform-methanol-water-acetic acid).

**Methyl Decyl Sulfone Diimine.** This compound was prepared from 0.3 mole of methyl decyl sulfide and 1.2 moles of chloramine in acetonitrile following the same procedure described above for the dodecyl homolog. The compound was isolated in 45% yield.

**Methyl Tetradecyl (and Hexadecyl) Sulfone Diimine.** These homologs could not be obtained in satisfactory yield in acetonitrile reaction medium, because the sulfide starting material crystallized from acetonitrile solution at the desired reaction temperature. They were, therefore, prepared in 2-propanol, in which the sulfides are more soluble in the cold. Tlc showed, however, that recrystallization failed to remove the sulfone imine impurity. It was necessary to resort to column chromatography on silica gel (described above) for purification.

**Thermal Decomposition and Hydrolysis Experiments.** These were carried out in sealed tubes immersed in a steam bath. In the case of the dimethyl homologs, the products were isolated by adding the reaction mixture to several volumes of 50% potassium carbonate and extracting with 2-propanol. It was shown that dimethyl sulfoxide, sulfone, sulfone imine, and sulfone diimine could all be recovered from aqueous solution in high yield by this technique. In 2 *N* acid, no recoverable products were found after 30 min at 100°. Decomposition products of the dodecyl compound in acid were unambiguously identified by comparison of gas chromatography retention times and infrared spectral data with those of authentic materials. Yields, where reported in the text, were determined by injecting several large samples (30–40  $\mu$ l) in the gc and weighing the fractions collected.

Decomposition experiments on the dodecyl homolog in 2.4 *N* HCl–6 *M* KI at 100° for 30 min gave  $\text{I}_2$  (1.2 moles/mole of diimine)

and a liquid which was principally methyl dodecyl sulfide (48%) containing dodecyl chloride and dodecyl iodide (combined yield 3%). However, when methyl dodecyl sulfone diimine was heated with 2 *N* HCl and worked up with a carbonate wash, a water-soluble long-chain potassium salt lacking an  $\text{S-CH}_3$  in the nmr was isolated, in addition to dodecyl chloride, and was shown to be potassium dodecanesulfinate by reaction in aqueous solution with methyl iodide. Methyl dodecyl sulfone, identified unambiguously by infrared spectra and gas chromatography retention time, was isolated. The experiment was repeated, and the dodecyl chloride and dodecanesulfonic acid yields were estimated to be 53 and 37%, respectively.

No dodecyl mercaptan was ever detected among the decomposition products (gas chromatography).

**Metal Complexing.** Solutions (0.1 *M*) of dimethyl sulfone diimine, trimethylamine oxide, or trimethylphosphine oxide solutions were mixed with an equal volume of 0.1 *M* solutions of the metal salts. The phosphine oxide caused no visible change with any salt but  $\text{VOSO}_4$  (blue  $\rightarrow$  green). The visible changes with diimine and amine oxide were indistinguishable:  $\text{VOSO}_4$ , blue  $\rightarrow$  green, gray precipitate;  $\text{Cr}(\text{NO}_3)_3$ , blue  $\rightarrow$  green;  $\text{MnCl}_2$ , no change;  $\text{FeCl}_3$ , yellow  $\rightarrow$  red-orange, prevented precipitation on standing which occurred in the control solution;  $\text{CoCl}_2$ , no change;  $\text{NiCl}_2$ , no change;  $\text{CuSO}_4$ , blue-green precipitate, identified as  $\text{Cu}_2\text{SO}_4(\text{OH})_2$  by the X-ray powder pattern;  $\text{ZnCl}_2$ , no change. Adding  $\text{CuSO}_4$  solutions to a concentrated solution of the sulfone diimine gave an obvious deepening of the blue color.

Addition of  $\text{AgNO}_3$  test reagent to any of the sulfone diimines in aqueous solution gave a gray precipitate, and a decrease in pH of the solution from ca. 8 to ca. 2.5. The precipitate did not form when the chloride test described above was used. Potentiometric titration with KOH of a system containing  $\text{AgNO}_3$  and  $(\text{CH}_3)_2\text{S}(\text{NH}_2)_2$  in 2.48:1 mole ratio gave a gradually sloping curve. The pH at 1 mole of KOH per mole of diimine was 4.8, and at 1.5 moles of KOH per mole of diimine was 6.8. Neither a precipitate nor a pH lowering was observed when dimethyl sulfone imine was mixed with  $\text{AgNO}_3$ .

**Solubility Curve.** The solubility of dimethyl sulfone diimine (Figure 4) was described by determining the temperature at which crystals separated on cooling and dissolved on heating with synthetic mixtures. The separating phase below the discontinuity is probably a quarter-hydrate. Nitrogen analyses on a sample crystallized from water and dried by blowing nitrogen over the sample at room temperature (which, incidentally, slowly evaporates the compound itself) gave values of 29.0, 28.9, and 29.2%; calculated for  $(\text{CH}_3)_2\text{S}(\text{CH}_2)_2 \cdot 0.25\text{H}_2\text{O}$ , 29.0%. The separating phase above the discontinuity is presumed to be anhydrous crystals.

**Acknowledgments.** The authors are particularly indebted to Mr. A. L. Voegelé for assistance in performing the synthetic experimental work, to Mrs. M. K. Sargent who performed most of the tlc analyses, and to Mr. G. Wayne Emmert for assistance in obtaining infrared and Raman spectra.

Lincomycin. II. Characterization and Gross Structure<sup>1,2</sup>

Ross R. Herr and George Slomp

*Contribution from the Research Laboratories of the Upjohn Company, Kalamazoo, Michigan. Received December 20, 1966*

**Abstract:** Physical and chemical characteristics of lincomycin, together with spectral data and examination of the products of hydrolysis and periodate oxidations, allow the postulation of a gross structure as a working hypothesis.

Lincomycin, as has been reported,<sup>3-6</sup> is a new antibiotic produced by an actinomycete designated *Streptomyces lincolnensis* var. *lincolnensis*, n.sp. Clinical use has shown it to be an effective agent for treatment of infections in humans.<sup>7</sup> This paper presents the general characteristics of the antibiotic and the preliminary degradations which led to the postulation of the gross structure as a working hypothesis.

Lincomycin is a basic compound in which the single amine group is tertiary with a  $pK_a'$  of 7.6. The free base is soluble in water and most organic solvents other than the hydrocarbons and has the empirical formula  $C_{18}H_{34}N_2O_6S$ . The crystalline hydrochloride salt, which is soluble in water and the lower alcohols, forms hydrates and was isolated as the hemihydrate,  $C_{18}H_{34}N_2O_6S \cdot HCl \cdot 0.5H_2O$ . Group analyses showed the presence of two C-methyl, one N-methyl, and no acetyl or methoxyl groups. The infrared absorption spectrum indicates multiple OH and NH groups and a mono-substituted amide function (amide I and II bands). Lincomycin shows no absorption maxima in the ultraviolet or visible regions.<sup>4</sup>

Although the nmr spectrum of lincomycin hydrochloride (Figure 1) is quite complex, with many overlapping areas, it provides some valuable information. An anomeric hydrogen is indicated by a doublet at 322 cps,<sup>8</sup> one C-methyl appears as a triplet at 53 cps, indicating two neighboring hydrogens, and the other C-methyl as a doublet at 70 cps, indicating one neighboring hydrogen. The N-methyl is readily recognized at 178 cps and, with no acetyl or methoxyl groups present, the remaining sharp singlet at 128 cps can be attributed to an S-methyl group. In addition, although the spectrum was not factorable, nor could complete assignments be made, area measurements to indicate the total number of hydrogens and their distribution were used to exclude certain otherwise possible structures.

These characterization data suggested a possible close structural similarity to celesticetin, an antibiotic isolated previously in these laboratories and on which

some structure work had been done.<sup>9</sup> For this reason, initial experiments on lincomycin paralleled those on celesticetin, and results substantiated this similarity. Subsequent work elucidated the complete structural relationship.<sup>10</sup>

Vigorous acid hydrolysis of lincomycin was accompanied by considerable charring but afforded two products, methyl mercaptan, isolated and identified as its 2,4-dinitrophenyl thioether, and an amino acid, isolated as a crystalline hydrated hydrochloride. Analysis and titration of the amino acid indicated an empirical formula  $C_9H_{17}NO_2 \cdot HCl \cdot 0.5H_2O$ . No color was produced with ninhydrin or isatin. A similar  $C_9$  amino acid from celesticetin had been identified as L-hygric acid (N-methylproline), and comparison of the nmr spectrum of the lincomycin moiety with that of a synthetic sample of DL-hygric acid<sup>11</sup> showed the new amino acid to be a *n*-propylhygric acid (Figure 2). The similarity of the spectra in the 100–300-cps region can be seen, together with the obvious differences in the lower frequency range. The presence in the spectrum of the lincomycin amino acid of a C-methyl group as a triplet at 45 cps and an area equivalent to four hydrogens in the 80-cps region representing the two methylene groups of the alkyl chain give a clear picture of a *n*-propyl group. The position and configuration of the alkyl group could not be determined from the spectrum, since the ring hydrogen multiplets could not be factored.

The specific rotation of the amino acid hydrochloride in water,  $[\alpha]_D -153^\circ$ , and the slight positive rotational shift of the free amino acid from  $[\alpha]_D -67^\circ$  in water to  $[\alpha]_D -62^\circ$  in 5 *N* hydrochloric acid suggested the L configuration, although this was not definite due to the presence of the second asymmetric center.<sup>12</sup> The position of the propyl group and the complete stereochemistry of the amino acid was determined by subsequent work.<sup>13</sup>

Although the sugar portion of the molecule is destroyed during acid hydrolysis, much could be deduced from other chemical and nmr data. The ease of removal of the S-methyl under acid conditions, plus the clear indication of an anomeric hydrogen by nmr, placed this as a glycosidic group. Acetylation of lincomycin showed the presence of four hydroxyls by formation

etra-O-acetate, as shown by group analyses and The nmr spectrum of the tetraacetate in chloro- solution showed four resolved acetyl methyl tions at 114, 119, 124, and 127 cps (Figure 3).

eriodate oxidations about 4 moles of periodate nsumed per mole of lincomycin. The quantita- however, was somewhat unreliable because of end points due to the influence of the oxidized group.<sup>14</sup> Replacement of the S-methyl group drogen on treatment with Raney nickel gave a ct designated anhydrolincomycitol, which cleanly ned 2 moles of periodate/mole. As expected, rolincomycitol showed no S-methyl group or ric hydrogen in its nmr spectrum (Figure 4). preparative scale, periodate oxidation of linco- followed by brief acid hydrolysis allowed isola- of glyoxal as its 2,4-dinitrophenylhydrazone. titration with alkali following periodate oxidation d the formation of 1 mole of formic acid. Based se data, plus the proton distribution data obtained he nmr spectrum, structure 1 was proposed as a le partial structure for lincomycin.

odate results require the three adjacent hydroxyls ring, with the glyoxal derived from carbons 1 and the formic acid from carbon 3. The nmr spec- Figure 1) shows that, other than the methyl hy- is, all the remaining hydrogens in the sugar porf the molecule are on carbons bearing negative i. Thus, the methyl group represented by the t at 70 cps is attached to a carbon holding one gen plus either an oxygen or nitrogen function. facts require the pyranose ring since any furanose ructure would either contain a tertiary hydroxyl

V. A. Bonner and R. W. Driski, *J. Am. Chem. Soc.*, 73, 3699

Figure 2. Nuclear magnetic resonance spectra of DL-hygric acid hydrochloride (synthetic) and the amino acid hydrochloride from lincomycin, in water.

and additional paraffin hydrogens which are not seen in the nmr spectrum or would not account for the formation of formic acid on oxidation. Another pyranose structure with a branched sugar skeleton is allowed by these data, but structure 1 was used as a working hypothesis, and the straight chain skeleton was confirmed by subsequent examination of degradation products.<sup>15</sup>

The relative positions of the amide function and the last hydroxyl group were uncertain. The fact that lincomycin and some of its degradation products give negative iodoform tests led us to postulate the positions shown in 1, but later nmr data was in better agreement with the reverse arrangement.<sup>16</sup> Subsequent chemical work showed conclusively that their true positions are the latter.<sup>15</sup>

Figure 4. Nuclear magnetic resonance spectrum of anhydrolincomycin hydrochloride in water.

## Experimental Section<sup>17</sup>

**Acid Hydrolyses.** (a) **For Methyl Mercaptan.** A solution of lincomycin hydrochloride (1 g) in 5 *N* sulfuric acid (10 ml) was refluxed and the evolved gases were passed through a mixture of 0.3 ml of 3.3 *N* sodium hydroxide (aqueous) and 3 ml of ethanol. To the resulting solution was added a solution of 1-chloro-2,4-dinitrobenzene (200 mg) in warm benzene (3 ml). The yellow crystals which formed immediately were collected and recrystallized from ethanol to give 58 mg of shiny yellow plates, mp 127–128; lit. for methyl 2,4-dinitrophenyl thioether, mp 128.<sup>18</sup> The infrared spectrum was identical with that of an authentic sample.

*Anal.* Calcd for  $C_7H_8N_2O_6S$ : C, 39.25; H, 2.83; N, 13.08; S, 14.97. Found: C, 39.03; H, 2.67; N, 12.84; S, 14.95.

(b) **For Propylhygric Acid.** A solution of lincomycin hydrochloride (2 g) in 6 *N* hydrochloric acid (50 ml) was refluxed for 30 min and then distilled to dryness. The dry residue was dissolved in water (20 ml) and extracted twice with chloroform (two 10-ml portions). The aqueous solution was diluted with 60 ml of water and extracted twice with butanol (two 20-ml portions). The aqueous solution was then evaporated to dryness and the dry residue was dissolved in ethanol (20 ml). The ethanolic solution was decolorized with carbon, and ether (100 ml) was added to the filtrate. A gummy precipitate which separated was removed by filtration and discarded. The filtrate was again treated with carbon, and additional ether (1000 ml) was added to the filtrate. After standing several weeks in the refrigerator crystals formed; yield 650 mg.

A sample for analysis was recrystallized several times from ethanol-ether. On heating, the crystals softened at about 123° and finally melted with decomposition at 160–170°. The  $pK_a$ 's in water were 2.4 and 10. The infrared spectrum in mineral oil suspension suggested a tertiary amino acid hydrochloride, hydrated, and had bands at 3530, 3460, 2720 (broad), 1740, 1225, 1210, 1190, 1150, 1120, 1105, 1040, 1025, 980, 925, 845, and 810  $cm^{-1}$ .

*Anal.* Calcd for  $C_9H_{17}NO_5 \cdot HCl \cdot 0.5H_2O$ : C, 49.87; H, 8.84; N, 6.46; Cl, 16.36; mol wt, 216.7. Found: C, 49.35; H, 8.55; N, 6.75; Cl, 16.96; mol wt (electrometric titration), 216.

**Lincomycin Free Base.** A solution of lincomycin hydrochloride (100 g) in deionized water (1700 ml) was adjusted to pH 10 by the addition of 5 *N* sodium hydroxide and extracted three times with chloroform (three 1700-ml portions). The extracts were combined and dried over sodium sulfate, and the chloroform was evaporated under reduced pressure while deionized water was added. The resultant aqueous solution was freeze dried to yield 85 g of white amorphous lincomycin base. Karl Fischer determination showed this material to contain 1.50% water. Analytical values shown are corrected for the water content, with actual values shown in parentheses. The optical rotation was  $[\alpha]_D^{25} +158^\circ$  (156°) (c 1, water). The nmr spectrum was very similar to that of the hydrochloride except that the N-methyl absorption of the free base was shifted 38 cps upfield as a result of the removal of the charge from the nitrogen.

*Anal.* Calcd for  $C_{18}H_{34}O_6N_2S$ : C, 53.18; H, 8.43; N, 6.89; S, 7.89; mol wt, 406.5. Found: C, 53.11 (52.31); H, 8.40 (8.44); N, 6.95 (6.83); S, 7.98 (7.86); mol wt (electrometric titration), 408 (415).

**Lincomycin Tetraacetate.** Lincomycin base (1.7 g) was acetylated with pyridine (50 ml) and acetic anhydride (25 ml) at room temperature. After 24 hr the excess reagents were removed under

(17) Melting points were determined on a Kofler hot-stage apparatus.  
(18) R. L. Shriner and R. C. Fuson, "The Systematic Identification of Organic Compounds," 2nd ed, John Wiley and Sons, Inc., New York, N. Y., 1940, p 225.

ed pressure and the residue was dissolved in methylene chloride and water. The mixture was neutralized with saturated sodium bicarbonate, phases were separated, and the aqueous layer extracted with methylene chloride. The combined methylene chloride extracts were washed until they were neutral and dried with sodium sulfate, and the solvent was evaporated under reduced pressure. The glassy residue did not crystallize and was therefore buted countercurrently for 500 transfers using the solvent in Skellysolve B-acetone-water in the ratio 7:16:3. The bution was analyzed by the determination of solids and showed a single peak with the center at tube 323,  $K = 1.8$ , which fit well with the theoretical curve. Tubes 310-350 were pooled and the solvents evaporated under reduced pressure. The residue, a glass which did not crystallize, was converted to the hydrochloride salt by boiling in ether and bubbling in hydrogen chloride. The hydrochloride which precipitated was collected by filtration and dissolved in a small amount of chloroform, which was then layered with ether and chilled in the refrigerator. Crystallization began at the intermediate ether was added gradually, and finally the layers were separated. The crystals were collected, recrystallized by the same procedure, and air dried, mp 226-233°;  $[\alpha]_D^{25} +149^\circ$  (c 1, water). The infrared spectrum was consistent with the formation of a tetrahydrate; the NH absorption at 3200  $\text{cm}^{-1}$  remained but the OH absorption at 3400-3600  $\text{cm}^{-1}$  had disappeared. Analyses indicated the crystalline hydrochloride as prepared to be a hemihydrate. *Calcd* for  $\text{C}_{17}\text{H}_{22}\text{N}_2\text{O}_6 \cdot \text{HCl} \cdot 0.5\text{H}_2\text{O}$ : C, 50.35; H, 5.81; N, 4.52; O, 27.09; S, 5.17; Cl, 5.72;  $\text{H}_2\text{O}$ , 1.45; acetyl, 7.8; equiv wt, 620. *Found*: C, 49.83; H, 7.57; N, 4.52; O, 27.10; S, 4.99; Cl, 5.81;  $\text{H}_2\text{O}$ , 1.72; acetyl, 25.53; equiv wt, 620.

**Iodate Oxidation of Lincomycin Hydrochloride.** (a) *Titration.* Titration of lincomycin hydrochloride by the Fleury-Lange procedure using 0.23 *M* sodium metaperiodate solution showed consumption of periodate varying from 3.5 to 5 moles because of fading points. Titration of the products of oxidation was carried out as follows. Two 45-mg samples of lincomycin hydrochloride each dissolved in 20 ml of water. Five milliliters of a 50-mg/ml solution of sodium metaperiodate in water was added to each beaker and the beakers were wrapped with foil. A blank, using 20 ml of water and 5 ml of the periodate solution, was similarly treated, standing at room temperature for 45 min, ethylene glycol (2 ml) as added to each beaker; the mixture was again let stand for 45 min. The solutions were then titrated with 0.02 *N* sodium hydroxide. A second blank containing 47.6 mg of lincomycin hydrochloride in 20 ml of water was also titrated with the sodium hydroxide. Comparison of the results indicated 1.2 moles of acid,  $\text{HIO}_4$ , formed per mole of lincomycin (lit. for formic acid is 3.75).

**Isolation of Glyoxal 2,4-Dinitrophenylhydrazone.** A solution of lincomycin hydrochloride (1 g) in 25 ml of water was added to a solution of sodium metaperiodate (2 g) in 75 ml of water. After stirring at room temperature for 1 hr, barium hydroxide solution was added until no more precipitate formed. The mixture was filtered and the filtrate was extracted with methylene chloride (three portions). The extracts were combined and concentrated under reduced pressure. The almost colorless oily residue was dissolved in ethanol (25 ml) and added to a hot solution of 2,4-

dinitrophenylhydrazine (1 g) in ethanol (75 ml). Concentrated hydrochloric acid (2.5 ml) was added and heating continued. The remaining undissolved reagent went into solution and almost immediately a precipitate began to separate. The product was collected, washed with ethanol, and air dried; mp 319-325° (lit.<sup>19</sup> for the glyoxal derivative 328°). It was identified as the 2,4-dinitrophenylhydrazone of glyoxal by comparison of its infrared and ultraviolet spectra with those of an authentic sample.

**Anhydrolincomycitol.** Raney nickel (W-3) was washed with water until the washings were neutral, and about 40 g of this nickel was added to a solution of lincomycin hydrochloride (5 g) in water (125 ml). The mixture was stirred and refluxed for 1 hr, at which time about 25 g of fresh, washed Raney nickel was added. Again the mixture was stirred and refluxed for 1 hr, and again 25 g of fresh nickel was added. After a third hour of stirring and reflux, the mixture was cooled and the nickel was removed by filtration. The filtrate was adjusted to pH 9.2 with sodium hydroxide and extracted exhaustively with chloroform (six 250-ml portions, then six 500-ml portions). The chloroform extracts were combined and the solvent was removed under reduced pressure. The glassy residue (2.6 g) was distributed for 300 transfers using the solvent system methyl isobutyl ketone-water-ethanol in the ratio 5:5:2. The distribution was analyzed by the determination of solids and showed a single peak, peak tube 82,  $K = 0.38$ , with an excellent fit to the theoretical curve. Tubes 65-100 were pooled and concentrated to an aqueous solution (10 ml) under reduced pressure. This concentrate was acidified with concentrated hydrochloric acid (ten drops) and acetone was added slowly while stirring until the solution became cloudy (140 ml of acetone). Another 60 ml of acetone was added, and scratching the flask induced crystallization. The crystals were collected and dried in a vacuum desiccator; 1.52 g. Addition of 150 ml of acetone to the mother liquor gave a second crop of crystals, 214 mg; total yield of anhydrolincomycitol hydrochloride, 1.73 g (38%). A sample for analysis was recrystallized from acetone-water, mp 206-210°. The nmr spectrum was consistent with the proposed removal of a thiomethyl glycosidic group; both the anomeric hydrogen doublet at 314 cps and the S-methyl singlet at 120 cps had disappeared. Analyses indicated the crystalline hydrochloride to be a hemihydrate. The compound showed no measurable optical rotation at the sodium D line.

*Anal.* *Calcd* for  $\text{C}_{17}\text{H}_{22}\text{N}_2\text{O}_6 \cdot \text{HCl} \cdot 0.5\text{H}_2\text{O}$ : C, 50.29; H, 5.81; N, 4.52; O, 27.09; S, 5.17; Cl, 5.72;  $\text{H}_2\text{O}$ , 1.45; acetyl, 7.8; equiv wt, 620. *Found*: C, 50.35; H, 5.84; N, 4.52; O, 27.19; Cl, 5.84;  $\text{H}_2\text{O}$ , 1.43; equiv wt, 396.

**Periodate Oxidation of Anhydrolincomycitol Hydrochloride.** Anhydrolincomycitol hydrochloride was titrated by the Fleury-Lange procedure using 0.23 *M* sodium metaperiodate solution. The consumption of periodate was, in hours (moles): 0.5 (2.00), 1.5 (2.06), 3.5 (2.00), 19 (2.00).

**Acknowledgments.** The authors wish to thank Mr. Forrest MacKellar for technical assistance and Mr. Raymond Anderson and his associates for the analytical results.

# Lincomycin. III.<sup>1a-c</sup> The Structure and Stereochemistry of the Carbohydrate Moiety

W. Schroeder, B. Bannister, and H. Hoeksema<sup>2</sup>

Contribution from the Research Laboratories of the Upjohn Company, Kalamazoo, Michigan. Received December 20, 1966

**Abstract:** Cleavage of lincomycin at the amide bond into methyl thiolincosaminide and an amino acid was readily effected in refluxing hydrazine. The carbohydrate structure was determined by various physical and chemical procedures to be an unbranched 6-amino-octose. The stereochemistry of six of its seven asymmetric centers was established by isolation of D-galactose  $\alpha$ -methylphenylhydrazone and N-2,4-dinitrophenyl-D-allo-threonine, following oxidative cleavages of the appropriate derivatives. The configuration of the thiomethyl group was assigned from considerations of optical rotations.

Partial structure 1 for lincomycin was derived in paper II<sup>1c</sup> of this series. The strenuous hydrolytic procedures employed therein freed the peripheral moieties, methyl mercaptan and a propylhygric acid, but failed to provide the intact carbohydrate. Hydrazine hydrate at reflux temperatures<sup>3</sup> efficiently cleaved the amide bond, liberating methyl thiolincosaminide (MTL) in high yield. MTL appeared to be the intact carbohydrate.

1

The amino acid fragment was isolated as the hydrazide which could be hydrolyzed in aqueous acid to the propylhygric acid described in the earlier work. To show that the vigorous reaction conditions had induced no rearrangements or racemizations in MTL, highly purified MTL was reacylated with the amino acid moiety. The reconstituted lincomycin so obtained was identical in every way with the antibiotic isolated from fermentations.

Consideration of the partial structure 1 led to working structure 2 for MTL.<sup>4</sup> Regardless of the ambiguity

2

(4) Hereafter, the complete structural formulas as ultimately determined will be employed, although some uncertainties, particularly that relating to substituents on C<sub>6</sub> and C<sub>7</sub> as illustrated in 2, actually persisted to the very end of this investigation.

of the C<sub>6</sub> and C<sub>7</sub> substituents, oxidative cleavage of the vicinal amino alcohol would provide an aldehyde capable of either oxidation or reduction to a known compound after removal of the thioaglycone. Thus, structural and stereochemical information concerning most of the MTL would be provided. Blocking of the ring hydroxyls of 2 to periodate cleavage would provide an intermediate suitable for cleavage at the desired position. Since an acetonide 3 of lincomycin itself formed

3

readily with ring hydroxyls as the most likely locations for the isopropylidene group, hydrazinolysis of this compound was expected to provide the desired intermediate (7). However, isopropylidenelincomycin proved completely resistant to hydrazinolysis and could be recovered unchanged following 140 hr of refluxing in hydrazine hydrate. Reasons for this are not completely clear. It may be due to the high degree of insolubility of the compound at reaction temperatures. Alternately, studies of models show that the back-side attack of the amide carbonyl by hydrazine is severely hindered when the conformation is such that the large acyl group is adjacent to the isopropylidene group. Hindrance to hydrazinolytic cleavage of amides has recently been reported.<sup>5</sup>

An alternate route to the desired intermediate was to convert MTL (4) to N-acetyl-MTL (5) with acetic anhydride in methanol. Subsequent treatment of 5 with acetone and sulfuric acid gave N-acetylisopropylidene-MTL (6) in good over-all yield. This compound underwent hydrazinolysis more readily, affording the key intermediate 7. Consumption by 7 of 3 moles of periodate produced acetaldehyde and a compound considered to be aldehyde 8.

Oxidation of 8 with nitric acid yielded a dibasic acid which was identified by infrared spectra and mixture melting points as mucic acid. Treatment of 8 with borohydride, followed by acid hydrolysis in the pres-

(5) M. Fujinaga and Y. Matsushima, *Bull. Chem. Soc. Japan*, **39**, 185 (1966).

ence of  $\alpha$ -methylphenylhydrazine, afforded D-galactose  $\alpha$ -methylphenylhydrazone, presumably *via* 9 which was not isolated. The isolation of the hydrazone in 58% (from 7) yield confirmed stereochemistry of carbons 2-5, as well as establishing the D series (see Chart I).

Chart I

Relative locations of nitrogen and oxygen and the stereochemistry on carbons 6 and 7 remained to be elucidated. Although lincomycin and MTL (and subsequently compounds 11, 15, and 16) failed to give an iodoform test, the nmr<sup>6</sup> spectrum of MTL favored assignment of nitrogen to C<sub>6</sub> and oxygen to C<sub>7</sub>. This issue was further clouded by the positive iodoform test obtained following nitrous acid deamination of 4. Efforts to resolve the impasse by periodate studies<sup>7</sup> in the open-chain series of compounds 11-16 (Chart II) were inconclusive.

The location of the groups was established by characterization of the ketone formed by oxidation of the hydroxyl in question. Thus, compound 6, obtained from MTL, was desulfurized with Raney nickel, affording 17, containing one ring hydroxyl which was inert to mild chromic acid oxidation and a side-chain hydroxyl. Such oxidation of 17 in either pyridine or glacial acetic acid yielded a crystalline ketone 18, dis-

playing carbonyl absorption at 1720 cm<sup>-1</sup>, which now gave a positive iodoform test. Furthermore, nmr studies of 17 and 18 show that the terminal methyl doublet of 17 at 1.10 and 1.21 ppm had disappeared in the spectrum of 18. Instead, a new singlet at 2.33 ppm was displayed. Thus, formulation A for the side chain cannot obtain, leaving the alternative B. Reduction of 18 with borohydride afforded a mixture from which iodoform again could not be obtained.

Confirmation of the above information as well as elucidation of the stereochemistry of carbons 6 and 7 were derived through the isolation of the terminal four carbons as an amino acid. Following numerous unsuccessful attempts to obtain such fragments from such intermediates as 14, 15, 16, or N-benzoylated 13 and 15, a single compound was finally isolated using 19, the dinitrophenyl (DNP) derivative of 15. After oxidation with periodate-permanganate mixture,<sup>8</sup> an amorphous product was purified by countercurrent distribution. The analytical data and paper chromatograms indicated an allothreonine-DNP, excluding the alternate choice, alanine-DNP. Rotational data, appearing in Table I, for the isomeric threonine and for L-allothreonine leave no doubt that the acid here isolated was D-allothreonine-DNP.

Table I. Comparison of Known 2,4-DNP Derivatives of the Isomeric Threonines with the 2,4-DNP Acid from Lincomycin

Compd	[M] <sub>D</sub> , degrees			Unknown
	D-Thre- onine	L-Thre- onine <sup>a</sup>	L-Allo- threo- nine <sup>a</sup>	
HOAc	+141	-141	-84	+83.4
NaHCO <sub>3</sub>	-305	+305	+305	-320 <sup>b</sup>

<sup>a</sup> J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1961, p 1564. <sup>b</sup> The error in this value is considered to be due to the necessity for a vacuum filtration of the test solution through a Millipore filter, resulting in some evaporative concentration.

The assumption of stereochemical assignment at carbon 1 was based originally on considerations of the nmr spectrum of MTL.<sup>1c</sup> That the configuration of the methylthio group was  $\alpha$ , however, was an important consideration in the process of factoring the entire spectrum and predicting galactose stereochemistry.

Proof of the axial configuration of the thioglycoside was obtained as follows. Acetylation of MTL in acetic anhydride-pyridine gave the pentaacetyl derivative 20, mp 218-220°, [ $\alpha$ ]<sub>D</sub> +223° (CHCl<sub>3</sub>). In ethanol-free chloroform solution, this pentaacetyl thioglycoside reacted rapidly with bromine<sup>9</sup> with the formation of the acetobromo derivative, considered to be the  $\beta$  anomer 21, but which could not be isolated crystalline.

The acetobromo sugar reacted readily with thiourea<sup>10</sup> in acetone and the isothiuronium salt, which was not isolated, was hydrolyzed and the resulting mercaptan methylated with methyl iodide in aqueous carbonate.

(9) (a) W. A. Bonner, *J. Am. Chem. Soc.*, **70**, 770, 3491 (1948); (b) F. Weygand and H. Ziemann, *Ann.*, **657**, 179 (1962); (c) M. L. Wolf from and W. Groebke, *J. Org. Chem.*, **28**, 2986 (1963).

(10) M. Cerny, J. Vrkoc, and J. Stanek, *Collection Czech. Chem. Commun.*, **24**, 64 (1959); M. Cerny and J. Pacak, *ibid.*, **24**, 2566 (1959).

(6) Nmr studies on MTL, which also led to the conclusion that the stereochemistry of C<sub>2</sub>-C<sub>5</sub> was galacto, appear in ref 1d.

(7) Both the sulfur [see L. Hough and M. I. Taha, *J. Chem. Soc.*, 3994 (1957)] and propylthio fragments can contribute to periodate complications.

A crystalline methyl pentaacetylthioglycoside, **22**, was isolated in excellent yield as the sole reaction product, mp 272–274°,  $[\alpha]_D^{25} +31^\circ$  ( $\text{CHCl}_3$ ). Since no opportunity exists in this sequence of reactions for a change in ring size to occur, stereospecific anomerization due to participation by the neighboring acetate group leads to the  $\beta$  anomer, showing a much lower positive rotation than pentaacetyl-MTL.

MTL, then, can best be represented by structure **23**, methyl 6-amino-6,8-dideoxy-1-thio-D-*erythro*- $\alpha$ -D-galacto-octopyranoside.

### Experimental Section<sup>11</sup>

**Hydrazinolysis of Lincomycin. Methyl Thiolinecosaminide (4).** A solution of 4.06 g (0.01 mole) of lincomycin base in 40 ml of hydrazine hydrate was refluxed for 21 hr. The excess hydrazine was then distilled off on the steam bath under reduced pressure (house vacuum). The residue set to semisolid mush of crystals when most of the hydrazine was gone. The residue was cooled and then stirred with acetonitrile until all of the lumps had broken up. The crystals were collected and washed with acetonitrile and then ether. After being dried *in vacuo* the crude product weighed 2.1 g (83%). This material was recrystallized by dissolving 1.5 g in a mixture of 5 ml of  $\text{H}_2\text{O}$  and 10 ml of methanol and adding 40 ml of 1-butanol. The resulting solution was filtered and the water and methanol were slowly evaporated *in vacuo*. The crystals which slowly separated from the butanol were collected, washed with butanol, and dried *in vacuo* to afford 700 mg of white crystals, mp 225–228°,  $[\alpha]_D^{25} +264^\circ$  ( $c$  0.718,  $\text{H}_2\text{O}$ ). Material crystallized in this manner was

(11) Melting points were determined on a Kofler micro hot-stage apparatus. Infrared spectra were consistent with the proposed structures.

scopic. The analytical sample contained 3.15% H<sub>2</sub>O by Fisher titration.

*al.* Calcd for C<sub>11</sub>H<sub>19</sub>NO<sub>5</sub>S + 3.15% H<sub>2</sub>O: C, 41.6; H, N, 5.42; S, 12.35; equiv wt (for hemihydrate), 262. Found: .86; H, 7.45; N, 5.63; S, 12.07; equiv wt (by titration), 257; = 7.5.

Material subsequently recrystallized from ten volumes of dimethylformamide was found not to be hygroscopic.

**Hydrolysis of Lincomycin.** Propyl-L-hygric Acid Hydrazide rate. Evaporation to dryness of the acetonitrile washes followed from procedures as described above yielded crude propyl-L-hygric acid hydrazide. A 5-g sample of crude 4-*n*-propylhygric hydrazide so obtained was dissolved in water and extracted several equal volumes of chloroform. The chloroform extracts were then reextracted with one-fourth volume of water. This procedure served to remove hydrazine and methyl thiolinoside from the hydrazide. The chloroform solution was then over sodium sulfate and evaporated on a rotary evaporator at 10 mm to leave 2.5 g of a heavy oily residue. This residue of partially esterified hydrazide crystallized on standing overnight, but the waxy, melting material was hygroscopic and resisted crystallization in a number of common solvents. An alcoholic solution when dried with picric acid, however, deposited a crystalline material which could be recrystallized from ethanol to afford an analytical sample.

*al.* Calcd for C<sub>11</sub>H<sub>19</sub>N<sub>3</sub>O<sub>5</sub>: C, 39.19; H, 3.92; N, 19.60. Found: C, 39.47; H, 3.71; N, 19.39.

**Conversion of 4-*n*-Propylhygric Acid Hydrazide to 4-*n*-Propyl-L-hygric Acid Hydrochloride.** A solution of 6 g of crude 4-*n*-propyl-L-hygric acid hydrazide in 20 ml of 6 *N* hydrochloric acid was refluxed for 2 hr. The reaction mixture was evaporated to dryness *in vacuo* and the gummy residue was washed thoroughly with boiling 70% ethanol until it became granular. This was dissolved in 20 ml of 2-propanol, treated with activated carbon, then diluted with 10 ml of acetone and treated again with carbon at boiling temperature. Finally, 50 ml of ether (and later a second 50-ml portion) was added to about crystallization for a total yield of 2.96 g. Recrystallization from 0.5 g of this from 15 ml of acetonitrile yielded crystals melting at 46.8° (c 3.42, H<sub>2</sub>O).

**Methyl N-Acetylthiolinosaminide (5).** Methyl thiolinosaminide (4) was suspended in 50 ml of methanol and treated under stirring with 3.75 ml of acetic anhydride at room temperature.

Most of the solid dissolved within a few minutes, and then replaced by a new precipitate. After stirring overnight at room temperature, the solid was removed at the pump, washed with methanol, and recrystallized from the same solvent, giving small needles, mp 243–245°; [α]<sub>D</sub><sup>25</sup> +248° (95% EtOH), +265° (c 1.0).

*al.* Calcd for C<sub>11</sub>H<sub>19</sub>O<sub>4</sub>NS: C, 44.72; H, 7.17; N, 4.74; S, 8.5. Found: C, 44.87; H, 7.10; N, 4.65; S, 10.99.

**Synthesis of Lincomycin.** A suspension of finely divided *n*-propyl-N-methylproline hydrochloride (4.14 g, 0.02 mole) in 150 ml of dry acetone was treated with 11.2 ml (0.08 mole) of triethylamine. The acid hydrochloride dissolved rapidly and triethylamine hydrochloride precipitated. To this suspension was added 2.3 g (0.02 mole) of *n*-propyl chloroformate and the mixture was stirred at room temperature for 1 hr. The resulting suspension was cooled in ice and filtered rapidly with suction into a 150-ml solution of 5.06 g (0.02 mole) of methyl thiolinosaminide (5) in 150 ml of water. The mixture was stirred well for 15 min.

Then air sucked through the filter for 45 min to evaporate most of the acetone. The remainder of the acetone was removed in a rotary evaporator at 40°. The remaining aqueous phase was extracted with 150-ml portions of methylene chloride and the extracts were dried with 30 ml of water and dried over MgSO<sub>4</sub>. The methylene chloride was removed *in vacuo* to leave 2 g of residue. This residue was dissolved in 10 ml of 1 *N* HCl and 20 ml of acetone was added. The insoluble material was removed by filtration and 180 ml of acetone was added to the filtrate. Crystals separated and were collected after standing for a while and washed with ether. After drying *in vacuo* at room temperature a yield of white crystals was 1.0 g. The substance was recrystallized from acetone–water and dried *in vacuo* at room temperature for analysis. Karl Fisher titration showed the presence of 0.615% of water; p*K*<sub>a</sub> in water = 7.55; [α]<sub>D</sub><sup>25</sup> +137° (c 1.044, H<sub>2</sub>O). Infrared spectrum was identical with that of a lincomycin reference standard.

*al.* Calcd for C<sub>18</sub>H<sub>33</sub>N<sub>2</sub>O<sub>6</sub>·0.615H<sub>2</sub>O: C, 47.61; H, 8.05; N, 6.17; S, 7.05; Cl, 7.82. Found: C, 47.41; H, 8.24; N, 6.76; S, 6.92; Cl, 7.75.

**3,4-O-Isopropylidenelincomycin (3).** A solution of 9.8 g of lincomycin in 150 ml of acetone was added to a solution of 9.8 g of *p*-toluenesulfonic acid monohydrate in 100 ml of acetone with good stirring. The mixture was stirred at ambient temperature for 1 hr, after which 100 ml of anhydrous ether was added and stirring was continued in an ice bath for 0.5 hr. The crystals were filtered off and dried *in vacuo* at 50°; yield 13.35 g (85.5%) of 3,4-O-isopropylidenelincomycin *p*-toluenesulfonate. An additional 1.15 g (7.4%) could be recovered from the mother liquors by adding 350 ml of anhydrous ether and chilling the solution for 1 hr. Conversion to the free base was achieved by suspending the combined crops in 200 ml of ether and shaking vigorously with 125 ml of 5% potassium bicarbonate solution. The aqueous layer was back-extracted with two 100-ml portions of ether. The ether extracts were washed with 50 ml of saturated sodium chloride solution and filtered through anhydrous sodium sulfate, and the ether was evaporated *in vacuo*, leaving 7.9 g (73.1%) of 3,4-O-isopropylidenelincomycin, which was then dissolved in 25 ml of ethyl acetate. The solution was concentrated to about 10–15 ml and allowed to stand at room temperature for several hours. After refrigerating overnight, the crystals were filtered from the solution and washed sparingly with cold ethyl acetate; yield 4.55 g (42.2%) of 3,4-O-isopropylidenelincomycin having a melting point of 126–128°, [α]<sub>D</sub><sup>25</sup> 102° (c 1, methylene chloride).

*Anal.* Calcd for C<sub>21</sub>H<sub>33</sub>N<sub>2</sub>O<sub>6</sub>S: C, 56.48; H, 8.58; N, 6.27; S, 7.18. Found: C, 56.37; H, 8.55; N, 6.01; S, 7.24.

**Methyl N-Acetylpropylidenethiolinosaminide (6).** A suspension of 5.3 g of finely powdered methyl N-acetylthiolinosaminide (5) was stirred for 60 hr at room temperature with 500 ml of acetone and 0.5 ml of concentrated H<sub>2</sub>SO<sub>4</sub>. Most of the starting material was still insoluble at this time. An additional 5 ml of H<sub>2</sub>SO<sub>4</sub> was added and the insoluble material dissolved rather rapidly. Stirring was continued for 30 min at room temperature. The solution was then added to a suspension of 150 g of barium carbonate in 100 ml of water and the mixture stirred until neutral. The barium salts were filtered off and washed with acetone. The filtrate was evaporated to dryness *in vacuo* at 50°. The residue was taken up in acetone–ether (10:1) and the insolubles were filtered off. The filtrate was evaporated to dryness and the residue was taken up in 100 ml of ethanol, which was then removed *in vacuo* to leave a yellow gum. The gum was dissolved in 20 ml of warm water containing a small amount of sodium carbonate, some insolubles were filtered off, and the filtrate was cooled. The crystals which formed were collected after standing in the refrigerator for 4 hr and washed with cold water. After drying *in vacuo* they weighed 2.0 g. A portion was recrystallized from water for analysis, mp 174–175°; [α]<sub>D</sub><sup>25</sup> +189° (c 0.4136, H<sub>2</sub>O).

*Anal.* Calcd for C<sub>14</sub>H<sub>23</sub>NO<sub>6</sub>S: C, 50.12; H, 7.52; N, 4.17; S, 9.55. Found: C, 49.87; H, 7.46; N, 4.11; S, 9.56; H<sub>2</sub>O, none by Karl Fisher.

**Methyl Isopropylidenethiolinosaminide (7).** A solution of 1 g of methyl N-acetyl-3,4-O-isopropylidenethiolinosaminide (6) in 10 ml of hydrazine hydrate was refluxed for 24 hr. The excess hydrazine was distilled off in a nitrogen stream on the steam bath. The crystalline residue was taken up in 5 ml of water and allowed to recrystallize. The crystals were collected and washed with cold water. After drying *in vacuo* the crystals weighed 450 mg. Recrystallization from ethanol afforded the analytical sample, mp 177–178°; [α]<sub>D</sub><sup>25</sup> +186° (c 0.689, H<sub>2</sub>O).

*Anal.* Calcd for C<sub>13</sub>H<sub>21</sub>NO<sub>5</sub>S: C, 49.12; H, 7.90; N, 4.78; S, 10.91. Found: C, 49.27; H, 8.0; N, 5.01; S, 10.92.

**Larger Scale Preparation of Methyl 3,4-O-Isopropylidenethiolinosaminide (7).** A suspension of 20 g of MTL (4) in 400 ml of methanol was stirred and 20 ml of acetic anhydride added. All of the solid dissolved in a few minutes, and then crystals of the N-acetyl derivative started to separate. After cooling in the refrigerator 1 hr the crystals were collected and washed with methanol. Drying *in vacuo* overnight afforded 19.3 g of N-acetate. This material was well powdered and suspended in 1500 ml of acetone. While stirring, 15 ml of concentrated H<sub>2</sub>SO<sub>4</sub> was added. After stirring for 1 hr at room temperature, all was in solution. After cooling in the refrigerator for an additional hour a slight excess (Hydron paper) of ammonia gas was passed in to neutralize the sulfuric acid. The ammonium sulfate was filtered off and washed with acetone. The colorless filtrate was evaporated *in vacuo* at 50° to a frothy gum. The yield of crude N-acetylisopropylidene derivative was 24.8 g. This crude material was dissolved in 210 ml of hydrazine hydrate. Crystals started to form, but they redissolved on heating. The

resulting solution was refluxed for 23 hr. The excess hydrazine was removed *in vacuo* on the steam bath. The residue was taken up in ethanol, some insolubles were filtered off, and the ethanol was then removed *in vacuo*. The crystalline residue was slurried with 50 ml of acetonitrile to break up lumps and the crystals were collected, washed with acetonitrile and ether, and dried *in vacuo*. The yield of first crop was 12.35 g. The filtrate upon evaporation afforded another 1.0 g of product. The total yield of material identical with that prepared previously was 13.35 g (57.5%).

**Mucic Acid from 7.** A solution of 3.2 g (slight excess of 3 equiv) of sodium periodate in 25 ml of warm water was cooled to room temperature and 1.5 g of methyl 3,4-O-isopropylideneethiolincosaminide was added simultaneously with good stirring. The MTL derivative dissolved rapidly and some salt precipitated (probably  $\text{NaIO}_3$ ). The temperature was maintained at room temperature by occasional cooling. The odor of acetaldehyde was strong. The solution was placed in a flask fitted with a sparger,  $\text{N}_2$  gas was passed through, and the acetaldehyde was converted to its 2,4-DNP derivative with Brady's reagent. After 3 hr the formation of 2,4-DNP had practically ceased. The yield of acetaldehyde 2,4-DNP was 750 mg (65%). The original reaction mixture was filtered from precipitated sodium iodate and a slight excess of barium acetate was added to the filtrate to remove the remainder of the iodate. The salts were removed and washed with water. The filtrate (50 ml) was treated with 15 ml of concentrated  $\text{HNO}_3$  and heated in an open beaker on the steam bath for 3 hr. By this time the solution had gone to dryness. The residue was dissolved in 15 ml of water and the resulting solution was permitted to stand overnight. After cooling in the refrigerator for 1 hr, the crystals which had separated were collected and washed with water, ethanol, and ether. After being dried *in vacuo* they weighed 250 mg and were identified by solubility, infrared spectrum, and direct comparison with mucic acid;  $[\alpha]_D^{20}$  0° (c 0.5, NaOH). An additional 205 mg of mucic acid separated from the filtrate on standing in the refrigerator for several days. The total yield was therefore 455 mg (41%).

**D-Galactose  $\alpha$ -Methylphenylhydrazone (10) from 7.** A solution of 6.4 g of sodium periodate in 75 ml of water was cooled and 3.0 g of isopropylidene-MTL (7) added all at once. The mixture was stirred and cooled to moderate the reaction. After standing in the refrigerator overnight, the salts were filtered off and barium acetate was added in slight excess to remove the remainder of the iodate. The salts were again removed and the filtrate was treated with 400 mg of sodium borohydride. After standing at room temperature for 1 hr, an additional 400 mg of borohydride was added. After 30 min, acetic acid was added dropwise to pH 6 to destroy excess borohydride. Some insoluble material was filtered off and about one-fifth volume of IR 120- $\text{H}^+$  resin added along with a few milligrams of sodium bisulfite to reduce some iodine liberated on acidification. The resulting suspension was heated on the steam bath for 4.5 hr, at which time a test for reducing sugar (Benedict) was at its maximum. Some Darco G-60 was added and the mixture was filtered. The filtrate was then reduced in volume to about 70 ml *in vacuo* at 50°. To this solution was added 2 g of sodium acetate, 2 g of sodium bisulfite, 1.5 g of  $\alpha$ -methylphenylhydrazine, and 1 ml of acetic acid. Crystals separated on standing. After overnight in the refrigerator, the crystals were collected, washed with water, and dried *in vacuo*. The slightly orange crystals weighed 900 mg, mp 187–189°. After standing an additional day in the refrigerator, the filtrate had deposited another 800 mg of product; total yield 1700 mg (58.5%). Recrystallization from hot water afforded colorless crystals of D-galactose  $\alpha$ -methylphenylhydrazone;  $[\alpha]_D^{20} +12.4^\circ$  (c 2.06, DMSO). An authentic sample of D-galactose  $\alpha$ -methylphenylhydrazone had  $[\alpha]_D^{20} +12.2^\circ$  (c 2.0, DMSO) and was identical in melting point and infrared spectrum with the material derived from isopropylidene-MTL.

**N-(4-Propyl-L-hygroyl)lincosamine Dimethyl Mercaptal (11).** In a three-necked flask equipped with a Dry Ice condenser, 150 ml of concentrated hydrochloric acid and 50 ml of methanethiol were chilled to 0°. After rapid addition of 15 g of lincomycin hydrochloride the mixture was vigorously stirred for 5 hr, then diluted with one volume of ice water and extracted with two 100-ml portions of pentane (or Skellysolve B). The extract was discarded. The 6 N hydrochloric acid solution was next partially neutralized by addition of a subequivalent amount (100 g) of potassium hydroxide pellets at 20–30° (Dry Ice-acetone cooling permitted rapid addition). The potassium chloride was removed by filtration. Next, 200 ml of chloroform was added to the filtrate which was then brought to pH 10 with sodium hydroxide. The chloroform layer was removed and a second extract was made with chloroform. The combined extracts were washed with three 50-ml portions of water

(emulsions), and the chloroform was evaporated *in vacuo* presence of water, transferring the product to the aqueous which was then freeze dried.

The freeze-dried product was crystallized from 75 ml of acetone to give 7.5 g, mp 134–140°. A second crystallizable material, mp 146–148°;  $[\alpha]_D^{20} -33^\circ$  (c 1, methylene chloride).

**Anal.** Calcd for  $\text{C}_{17}\text{H}_{25}\text{N}_2\text{O}_6\text{S}_2$ : C, 50.19; H, 8.42; N, 5.14. Found: C, 50.15; H, 8.20; N, 5.94; S, 14.31.

**N-(4-Propyl-L-hygroyl)-1-deoxyllincosaminol (12).** A susp of 100 g of W-3 Raney nickel (washed to pH 7 with water washed three times with absolute ethanol) was stirred and to reflux in 1 l. of absolute ethanol with 15 g of the me (11). After 4 hr the hot reaction mixture was filtered a nickel was washed with 600 ml of hot ethanol. The cor filtrate and washings were evaporated to dryness. A five countercurrent distribution at 60 ml/phase was run in the 1-butanol-water, moving the upper phase. The contents of 4 and 5 were evaporated to dryness (7 g) and crystallized from 10 ml of ethyl acetate (5.7 g), mp 105–108°.

**Anal.** Calcd for  $\text{C}_{17}\text{H}_{25}\text{N}_2\text{O}_6$ : C, 56.33; H, 9.46; N, 3.61. Found: C, 56.23, 56.29; H, 9.16, 9.30; N, 7.68.

**1-Deoxyllincosaminol (13) by Acid Hydrolysis.** A solution of N-(4-propyl-L-hygroyl)-1-deoxyllincosaminol (12) was under reflux in 50 ml of 4 N sulfuric acid for 4 hr. The solution cooled, brought to pH 8 with saturated barium hydroxide solution and filtered. The filtrate was passed through a 0.75-in. c containing 10 g of Dowex 2 in the hydroxyl cycle, and the solution was freeze dried, yielding 200 mg of white solid. A 120-mg sample was crystallized from absolute ethanol to yield 40 mg of product, mp 177–185°.

**Anal.** Calcd for  $\text{C}_8\text{H}_{11}\text{NO}_5$ : C, 45.92; H, 9.15; N, 6.69; wt, 209.24. Found: C, 46.29; H, 9.24; N, 6.40; equiv weight titration showed 1 basic function,  $\text{pK}_a' = 8.5$ .

**1-Deoxyllincosaminol (13) by Hydrazinolysis.** A 5-g quantity of compound 12 was heated under reflux for 6 days in 100 ml of zinc hydrate. The hydrazine was evaporated *in vacuo* and the residue was crystallized in two crops from 2 ml of water in 75 absolute ethanol; yield 60%.

**N-Benzoyl-1-deoxyllincosaminol.** To 700 mg of 1-deoxyllincosaminol (13) in 50 ml of absolute ethanol was added 1 g of benzoic anhydride. This was stirred until all dissolved and until the precipitate was completely formed. After overnight standing at room temperature 730 mg (70% yield) of white crystals was obtained, mp 188–190°.

**Anal.** Calcd for  $\text{C}_{18}\text{H}_{21}\text{NO}_6$ : C, 57.49; H, 7.40; N, 5.11. Found: C, 57.33; H, 7.45; N, 4.22.

**N-Acetyl-1-deoxyllincosaminol (14).** To 1 g (0.0048 mole) of 1-deoxyllincosaminol (13) in 100 ml of methanol was added 0.01 mole of acetic anhydride at 5°. This mixture was stirred until everything dissolved, and then refrigerated. After 20 hr 1 ml of ether was added, and the precipitate was filtered. The mother liquor was dried and the solid was recrystallized from 30 ml of absolute ethanol, yielding 630 mg of white crystals, mp 174–176°.

**Anal.** Calcd for  $\text{C}_{18}\text{H}_{21}\text{NO}_6$ : C, 47.39; H, 8.43; N, 5.18. Found: C, 48.09; H, 8.27; N, 5.43.

**Lincosamine Dimethyl Mercaptal (15).** A 10-g quantity of compound 11 in 100 g of hydrazine hydrate was heated under reflux for 6 days. The hydrazine hydrate was evaporated *in vacuo* on a nitrogen ebullator. The residue was crystallized from hot acetonitrile (100 ml) in two crops, for a total of 4.3 g (64% yield). The analytical sample was further crystallized from absolute ethanol, yielding a sample, mp 142–144°;  $\text{pK}_a' = 7.95$  in water.

**Anal.** Calcd for  $\text{C}_{18}\text{H}_{21}\text{NO}_6\text{S}_2$ : C, 39.84; H, 7.69; N, 5.11. Found: C, 39.74; H, 7.09; N, 5.20; S, 20.54; equiv wt, 320.

**N-Benzoyllincosamine Dimethyl Mercaptal.** A solution of (0.006 mole) of 15 in 100 ml of ethanol was heated under reflux for 1 hr with 3.6 g (0.016 mole) of benzoic anhydride. The reaction mixture was evaporated to dryness and the residue washed with absolute ethanol. Recrystallization from acetone gave 300 mg, mp 182–184°.

**Anal.** Calcd for  $\text{C}_{17}\text{H}_{21}\text{NO}_6\text{S}_2$ : C, 50.35; H, 6.71; N, 5.11. Found: C, 50.34; H, 6.81; N, 3.67; S, 15.96.

**N-Acetylincosamine Dimethyl Mercaptal (16).** A 1-g (0.006 mole) quantity of compound 15 suspended in 30 ml of methanol was stirred with 1 ml (0.011 mole) of acetic anhydride at room temperature for 2 hr. During this time, the starting material dissolved. Upon dilution with 20 ml of ether crystallization occurred, yielding 660 mg (59%) of dried, ether-washed, solid, mp 177–179°. Recrystallization from 15 ml of absolute ethanol gave 0.5 g mp 179–179.5°.

*Anal.* Calcd for  $C_{15}H_{22}NO_6S_2$ : C, 41.96; H, 7.34; S, 18.67. Found: C, 41.92; H, 7.18; S, 19.15.

**N-Acetyl-1-deoxylincosaminol (14) by Desulfurization.** From 2.49 g (0.007 mole) of 16 and ca. 50 g of nickel catalyst, refluxed 10 hr in 200 ml of absolute ethanol, was obtained 1 g (0.004 mole) of N-acetyl-1-deoxylincosaminol, identical with that above.

**N-Acetyl-3,4-O-isopropylidene-1-deoxylincosamine (17).** A 15-g quantity of methyl N-acetyl-3,4-O-isopropylidene-thiolincosaminide (6) was heated under reflux for 7 hr with 100 ml, loosely packed, of Raney nickel in 500 ml of ethanol. The mixture was filtered and the catalyst was washed with a total of 1 l. of boiling ethanol. The filtrate and washings were combined and evaporated to dryness, leaving a partially crystalline residue. This residue was purified by countercurrent distribution, 200 transfers, in the system 1-butanol-water. A major fraction,  $K = 0.48$ , was isolated by evaporation to give a white crystalline solid, mp 220–235° dec,  $[\alpha]_D^{+70}$  (c 1, 50% ethanol). This material gave a negative iodoform test.

*Anal.* Calcd for  $C_{15}H_{22}NO_6$ : C, 53.96; H, 8.09; N, 4.84. Found: C, 53.87; H, 8.23; N, 5.67, 4.92.

**N-Acetyl-3,4-O-isopropylidene-7-dehydro-1-deoxylincosamine (18).** **A. Oxidation in Pyridine.** To a solution of 1 g (0.0034 mole) of compound 17 in 10 ml of pyridine and 1 ml of water was added 1 g (0.0066 mole) of chromic oxide in 7 ml of pyridine and 1 ml of water. The mixture was stirred overnight, then added to a solution of 125 ml of ether and 125 ml of ethyl acetate. After standing 3 hr, this mixture was filtered and the filtrate was evaporated to dryness. The residual crystalline material was triturated with acetone and dried, yielding 225 mg of crystalline material. A second crop of 50 mg was recovered from the filtrate by countercurrent distribution in 1-butanol-water,  $K = 0.78$ . On recrystallization from acetone, a total of 185 mg of material was recovered which melted at 205–210°. This material showed new infrared absorption at  $1730\text{ cm}^{-1}$ , and the nmr spectrum showed a new signal at 2.35 ppm. This product gave a positive iodoform test. Upon treatment of the product with sodium borohydride in methanol, the iodoform test again was negative. *Anal.* Calcd for  $C_{15}H_{22}NO_6$ : C, 54.34; H, 7.37; N, 4.88. Found: C, 54.39; H, 7.59; N, 5.06.

**B. Oxidation in Glacial Acetic Acid.** To a solution of 1 g (0.0034 mole) of compound 17 in 10 ml of glacial acetic acid was added 1 g (0.0066 mole) of chromic oxide in 10 ml of acetic acid. The mixture, which warmed immediately, was stirred overnight. A 250-ml solution of ethyl acetate and ether (1:1) was added and the mixture was filtered, then evaporated to dryness. Trituration of the residue with acetone produced 40 mg of white crystals identical with those obtained from the pyridine oxidation.

**N-(2,4-Dinitrophenyl)lincosamine Dimethyl Mercaptal (19).** To 1 g (0.0033 mole) of lincosamine dimethyl mercaptal in 20 ml of 50% ethanol was added 0.5 g of sodium bicarbonate and 1 g (0.0054 mole) of 1-fluoro-2,4-dinitrobenzene, the latter in 10 ml of ethanol. After 2 hr of stirring, the mixture was evaporated to dryness and the residue was leached with 50 ml of benzene, which was then discarded. Upon washing the residue twice with 25 ml of water, 1.2 g of yellow solid remained. This was recrystallized from boiling acetone to give a total of 820 mg of yellow crystals, mp 138–140° dec.

*Anal.* Calcd for  $C_{16}H_{20}N_4O_8S_2$ : C, 41.10; H, 5.39; N, 8.99; S, 13.72. Found: C, 41.12; H, 5.38; N, 8.69; S, 13.33.

**Isolation of D-Allothreonine. Oxidative Cleavage of N-2,4-Dinitrophenyllincosamine Dimethyl Mercaptal.** A suspension of 4.3 g (0.0092 mole) of N-2,4-dinitrophenyllincosamine dimethyl mercaptal (19), 30 g of sodium metaperiodate, 3 g of sodium carbonate, and 650 mg of potassium permanganate in 1900 ml of water was stirred 6 hr. The mixture was extracted with 700 ml of ether, then acidified and further extracted with 200 ml of ether. The combined extracts, washed with 100 ml of water, were then dried over sodium sulfate and finally evaporated to dryness. The residue was taken into 50 ml of ether and washed with 50 ml of 5% bicarbonate, then with water. After acidification and reextraction of the alkaline layer, the dried (magnesium sulfate) ether solution was evaporated to dryness and the residue was subjected to countercurrent distribution in the system ethyl acetate-cyclohexane-95% ethanol-water (1:1:1:1, v/v). The contents of tubes 270–360 ( $K = 1.28$ ) were pooled and isolated by evaporation to an aqueous phase and freeze drying to yield 175 mg of yellow amorphous solid, which failed to

crystallize;  $[M]_D -320^\circ$  (4% sodium bicarbonate solution),  $+83^\circ$  (glacial acetic acid). Paper chromatographic comparison with DL-allothreonine-DNP and DL-threonine-DNP in the system 1-butanol-water-ethanol (4:5:1, v/v, use upper phase) showed similar  $R_f$  values for DL-allothreonine and the unknown compound (0.64), while that of threonine was lower (0.61).

*Anal.* Calcd for  $C_{10}H_{11}N_3O_7$ : C, 42.11; H, 3.89; N, 14.73. Found: C, 42.12; H, 4.19; N, 13.93.

**Iodoform from Nitrous Acid Treated Methyl Thiolincosaminide.** A solution of 100 mg of MTL in 1 ml of water and five drops of acetic acid was treated with 100 mg of sodium nitrite in portions over a 2-min period at room temperature. Gas evolution was vigorous and the solution turned pink. After standing at room temperature for 2 hr, 5 ml of 2 N sodium hydroxide and seven 1-ml portions of  $I_2$ -KI solution were added. Iodoform started to precipitate immediately. After cooling in the refrigerator for 2 hr, the precipitate was collected and dried in air. The yield of iodoform melting at 121–122° (Kofler) was 60 mg (39%).

The control experiment which contained no sodium nitrite gave no evidence of iodoform production.

**Pentaacetyl-MTL (22) (Methyl 6-N-Acetyl-2,3,4,7-tetra-O-acetyl-1-thio- $\alpha$ -lincosaminide).** Methyl 1-thio- $\alpha$ -lincosaminide (3.0 g) was acetylated by allowing a solution in pyridine (50 ml) and acetic anhydride (25 ml) to stand overnight at room temperature. Solvent was removed on the rotating evaporator at 40° (15 mm), and the syrupy residue was distributed between water and methylene chloride. The organic extract, after washing with dilute hydrochloric acid (1 N), water, and saturated aqueous sodium bicarbonate and drying over anhydrous sodium sulfate, was taken to dryness *in vacuo*, giving a colorless crystalline residue which was recrystallized from ethyl acetate-Skellysolve B to give rods, showing a double melting point of 210–212 and 218–200°;  $[\alpha]_D^{+223}$  (c 0.906,  $CHCl_3$ ).

*Anal.* Calcd for  $C_{16}H_{20}NO_{10}S$ : C, 49.22; H, 6.31; N, 3.02; S, 6.92. Found: C, 49.10; H, 6.57; N, 3.23; S, 6.91.

**Pentaacetyl- $\alpha$ -MTL (22) (Methyl 6-N-Acetyl-2,3,4,7-tetra-O-acetyl-1-thio- $\alpha$ -lincosaminide).** The above  $\alpha$ -pentaacetate (2.0 g, 4.3 mmoles), dissolved in ethanol-free chloroform (50 ml), was stirred magnetically and a solution of bromine (1.11 g, 0.36 ml, 6.9 mmoles) in the same solvent (20 ml) was added over the course of 10 min (Drierite tube). After stirring for an additional 15 min, no trace of starting material could be detected by thin layer chromatography ( $SiO_2$ , ethyl acetate-Skellysolve B, 1:1). Solvent was removed on a rotating evaporator at 40° (7 mm), giving a yellow-orange syrup which was redissolved in chloroform, the solvent removed as above, and the process repeated twice more, giving a colorless syrup which could not be induced to crystallize. This procedure removes the methylsulfinyl bromide.

A solution of this syrup in acetone (analytical reagent, 25 ml) was heated under reflux (Drierite tube) with thiourea (656 mg, 8.6 mmoles) for 1 hr. After cooling, potassium carbonate (680 mg), sodium bisulfite (860 mg), water (10 ml) and methyl iodide (3.06 g, 1.34 ml, 21.6 mmoles) were added, and the mixture was stirred vigorously for 3 hr at room temperature.

The acetone was removed *in vacuo*, and the residue was distributed between water and chloroform. The aqueous layer was extracted thoroughly with chloroform, and the combined extracts were washed twice with water and dried over anhydrous sodium sulfate. Removal of the solvent on a rotating evaporator at 40° (7 mm) gave a colorless solid (1.48 g) showing only one spot on thin layer chromatography ( $SiO_2$ , ethyl acetate-Skellysolve B, 1:1). The solid crystallized from ethyl acetate-Skellysolve B in colorless platelets, mp 272–274° (1.12 g, 56%), unchanged by further crystallization. Countercurrent distribution of the crude product in the system water-acetone-methyl ethyl ketone-cyclohexane (3:5:4:4, v/v) showed only one material, of  $K = 1.14$ , to be present;  $[\alpha]_D^{+31}$  (c 0.680,  $CHCl_3$ ).

# Lincomycin. IV. Nuclear Magnetic Resonance Studies on the Structure of Lincomycin, Its Degradation Products, and Some Analogs<sup>1</sup>

G. Slomp and F. A. MacKellar

Contribution from the Research Laboratories of the Upjohn Company, Kalamazoo, Michigan. Received December 20, 1966

**Abstract:** The contributions of nmr spectroscopy to the determination of the structure of lincomycin are reported. The amino acid portion was partially identified by nmr by comparison with synthetic samples. The structure of the sugar portion was independently determined by analysis of nmr spectra. The observation of an unusual intramolecular hydrogen bonding yielded the configuration of the sugar by conformational analysis. The spectra of some analogs and degradation products are correlated with their structures and conformations.

The structure of lincomycin,<sup>2</sup> an important new antibiotic with activity against gram-positive organisms, was the subject of a brief communication from these laboratories.<sup>3</sup> The present paper describes the nmr studies on lincomycin, some degradation products, and some analogs.

The nmr spectrum of lincomycin hydrochloride ( $C_{18}H_{35}N_2O_6SCl$ ) (Figure 1) is complex, containing many superimposed multiplets which were difficult to factor. There are several prominent signals which can be interpreted, but the severe overlapping, especially in the carbinol hydrogen region, makes complete interpretation impossible. The spectrum observed at 100 Mc<sup>4</sup> is not greatly different, indicating the close proximity of the shifts of the carbinol hydrogens. Attention was therefore turned to degradation products and derivatives.

Chemical experiments<sup>5</sup> showed that the molecule could be hydrolyzed at the amide linkage into an amino acid ( $C_9H_{17}NO_2$ ) (I) and an amino thio sugar (methyl thiolincosaminide, MTL) ( $C_9H_{19}NO_5S$ ) (II). Various aspects of the structures of these two compounds were determined by nmr, and when combined with chemical information the complete structure for the antibiotic was determined.

**Amino Acid Portion.** The nmr spectrum of the amino acid moiety (I) is shown in Figure 2. The material was thought to be a propyl-substituted hygric acid by comparison with known L-hygric acid.<sup>6</sup> The location and configuration of the alkyl group could not be determined from the spectrum because the 2- and 5-hydrogen multiplets could not be factored. The 2-hydrogen multiplet was an unsymmetrical three-line pattern with some additional absorptions between the three peaks. It could be rationalized as several partly superimposed doublets, each arising from the 2-hydrogen of molecules having a different ring conformation or different N-methyl configurations.

Similar reasoning might also apply to the 5 $\beta$ -hydrogen resonance. Subsequent experiments at increased temperature<sup>7</sup> showed that at 100° the 2-hydrogen resonance collapsed to a regular triplet ( $J = 9.0$  cps) and the 5 $\beta$ -hydrogen resonance became a doublet of doublets ( $J = 5$  and 10 cps). The original spectrum was regenerated when the sample returned to room temperature. Abraham and McLauchlan indeed found such ring buckling in the closely related *cis*- and *trans*-4-hydroxy-L-prolines<sup>8</sup> and further concluded that the latter was a mixture of conformers.<sup>8c</sup>

A synthetic sample of D-*cis*-4-propylhygric acid gave a spectrum which appeared to represent only one conformer (Figure 3). It was noted from the nmr spectrum that a sample of the unknown hygric acid was unexpectedly isomerized to the *cis*-4-propylhygric acid. This focused attention on the possibility that the unknown acid was the 4-*trans* isomer and that it had epimerized at C-2 in this experiment.

The structure of the amino acid was proved as L-*trans*-4-*n*-propylhygric acid (I) by synthesis and degradation.<sup>9</sup>

The analogous *trans*-4-methylproline reported by Abraham and co-workers<sup>8c</sup> gave an nmr spectrum uncomplicated by conformers as did also the amide of *trans*-4-propylhygric acid hydrochloride and the quaternary analog *trans*-4-propylstachydrine (the betaine of I). L-Proline gave a spectrum similar to that of I with conformational complications. This was not noted by Abraham, *et al.*,<sup>8c</sup> in their analysis of this spectrum. We plan to investigate this isomerism further.

**Amino Thio Sugar Portion.** The nmr spectrum of MTL (II) in deuterium oxide (Figure 4) showed absorptions for six kinds of hydrogen, as follows: (a) a doublet

NMR SPECTRUM OF LINCOMYCIN HYDROCHLORIDE

Figure 1. Nmr spectrum of lincomycin hydrochloride.

NMR SPECTRUM OF AMINO ACID PORTION (L-4-TRANS-N-PROPYLHYGRIC ACID, HYDROCHLORIDE)

Figure 2. Nmr spectrum of amino acid portion (L-4-trans-n-propylhygric acid hydrochloride) in D<sub>2</sub>O.

of area 3 at 68.0 cps,<sup>10</sup>  $J = 6.5$  cps, indicative<sup>11</sup> of a carbinol methyl group coupled to only one neighboring hydrogen; (b) a singlet of area 3 at 127 cps, assigned to the S-methyl group; (c) a doublet of doublets of area 1 at 188.5 cps,  $J = 10.5$  and 3.0 cps, indicative of a carbamine hydrogen coupled differently to two neighbors; (d) a group of resonance lines with a total area of 5, lying between 212 and 256 cps, arising from the carbinol hydrogens of the sugar; (e) the HOD line at 276 cps, containing the resonances of six exchangeable hydrogens on oxygen and nitrogen; and (f) a doublet of area 1 at 320 cps,  $J = 5.5$  cps, attributed to the anomeric hydrogen of the sugar. The multiplets are expanded for further study in Figure 5.

The nmr spectrum of MTL contained evidence that the molecule was a sugar. The presence of an anomeric hydrogen signal suggested an aldose, but aldoses are usually mixtures of many isomeric forms. The absence of mixture characteristics and the presence of a methylthio group suggested it was a methyl thioglycoside. The size of all the couplings and the general lack of sharpness suggested the rigidity of an aldopyranoside rather than a furanoside.<sup>12</sup>

The spectrum was empirically factored as much as possible using a dividers and making use where possible of the line shapes of the simple multiplets to evaluate  $J/\delta$  frequency and to determine  $\delta$  frequency (see Figure 5). The empirical factoring was subsequently confirmed

(10) Spectra were calibrated in cps units at 60 Mc, downfield from internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (SDSS) [G.V.D. Tiers and R. I. Coon, *J. Org. Chem.*, **26**, 2097 (1961)].

(11) K. Nukada, *et al.*, *Anal. Chem.*, **35**, 1892 (1963).

(12) Furanosides owing to their rapid ring conversion often give sharp spectra, and most of the coupling constants are of an averaged magnitude which is about 3 cps.

NMR SPECTRUM OF ISOMERIC AMINO ACID (D-4-CIS-N-PROPYLHYGRIC ACID, HYDROCHLORIDE)

Figure 3. Nmr spectrum of isomeric amino acid (D-4-cis-n-propylhygric acid hydrochloride) in D<sub>2</sub>O.Figure 4. Nmr spectrum of methyl thiolincosaminide in D<sub>2</sub>O.

The methyl group embodying the 8-hydrogens<sup>13</sup> absorbed as a doublet at 68 cps. These hydrogens were therefore coupled to one neighboring hydrogen at C-7. The absorption of this 7-H was found at 245 cps, again in the carbinol hydrogen region, and C-7, therefore, bears one hydrogen and one hydroxyl group. The 7-H absorption was actually a doublet of quartets and in addition to the coupling to the three hydrogens at C-8 it was further split ( $J_{6,7} = 9.25$  cps) by one hydrogen at C-6. The absorption of this 6-H was accordingly found at 188 cps, in the carbamine hydrogen region. Thus, C-6 bears one hydrogen and one amine group. This 6-hydrogen absorption was actually a doublet of doublets with the same  $J_{6,7}$  but with a second coupling ( $J_{5,6} = 3.75$  cps) to one neighboring hydrogen at C-5. The absorption of this 5-H could be extracted from the spectrum only by spin decoupling<sup>7</sup> and it was observed at 228 cps, in the carbinol hydrogen region, but again this multiplet could not be factored. Thus, C-5 bears one hydrogen and one oxygen substituent which in this case must be the pyran ring (*vide supra*).

The similarity of the shift of the 4- and 5-hydrogens apparently resulted in a very closely coupled multiplet which was not factored by empirical procedures. Such a multiplet would have an intense center at about 234 cps as shown in Figure 5, but the outlying portions would be weak and would not be seen in the spectrum.

Since all the peaks in the spectrum have been accounted for and all the allotted hydrogens have been used, it remains to connect C-4 and C-5 to yield structure II for this sugar. This analysis independently

confirmed earlier chemical evidence<sup>6</sup> that MTL was a thiomethyl pyranoside of an aminodideoxyoctose but disagreed in the position of the  $\text{NH}_2$  substituent.<sup>14</sup>

The data so far obtained also provided some information regarding the conformation and configuration of MTL. In a pyranoside ring some deformation is possible, as for example in  $\beta$ -glucopyranose,<sup>15</sup> and the dihedral angles are not always exactly 60 or 180°. Even though the Karplus relationship does not yield *exact* dihedral angles from coupling constants,<sup>16</sup> the *magnitude* of the calculated angle does allow a distinction between neighboring hydrogens that are diaxial *vs.* those which are diequatorial or axial-equatorial. The observed coupling constants are, therefore, summarized in Table I, and the appropriate conformational

(13) The empirical formula and subsequent reasoning (*vide infra*) showed that the molecule terminated with C-8.

(14) The negative iodoform test<sup>6</sup> required the  $\text{NH}_2$  group to be at C-7, but this test was subsequently shown to be anomalous.

**Table I.** Couplings<sup>a</sup> and Possible Conformations of the Sugar Hydrogens<sup>b</sup>

$J_{\text{H}}$	Cps	Conformational relationship	Dihedral angle, deg	
			Calcd	Found <sup>c</sup>
1,2	5.5	<i>ea</i> or <i>ee</i> <sup>d</sup>	33 or 127	60
2,3	10.5	<i>aa</i>	180	161
3,4	3.0	<i>ae</i> or <i>ee</i>	50 or 112	42
4,5	?	?	?	60
5,6	3.75	<i>ae</i> or <i>ee</i>	46 or 117	45
6,7	9.25	<i>aa</i>	150	163
7,8	6.5	Free rotation	...	...

<sup>a</sup> The coupling constants are simply first-order values obtained from the spacings in the spectra. Some of these approximate values may thus be in error by as much as 0.5 cps but this is not serious since exact fitting of angles was not sought. <sup>b</sup> The italic values were the ones that fit the final structure. <sup>c</sup> Observed in the Dreiding model of Ia. <sup>d</sup> *a* = axial, *e* = equatorial.

relationships have been deduced from the Karplus angles.

The configuration of the sugar can now be deduced from the dihedral angle data of Table I. Since the 2-H-3-H dihedral angle must be about 180°, these two hydrogens must be *trans* diaxial. A chair-formed pyranose ring was arbitrarily drawn in the D form and axial hydrogens were placed at carbons 2 and 3. Now if 2-H and 3-H are axial, the 1-H-2-H and the 3-H-4-H relationships cannot be equatorial-equatorial but must be equatorial-axial and axial-equatorial, respectively. Equatorial hydrogens were placed at carbons 1 and 4. Now the 4-H-5-H angle is not known because these multiplets could not be factored. However, one may assume that the alkyl chain at C-5 is equatorial because this is the more stable form which is reached by ring conversion between the two possible chair forms. Thus, the 5-H must be axial and the ring has the  $\alpha$ -galactoside configuration.

It was noteworthy that the signals arising from the 6- and 7-hydrogens were not very sharp. This was observed by comparing their ringing with that from the methyls. Also, the coupling constants of the 5-, 6-, and 7-hydrogens were not about 7 cps as would be expected for a freely rotating side chain. It was therefore concluded that this chain was held rigid, in one preferred conformation. Steric effects observed from Catalin models did not seem to be serious enough to bring about this rigidity, but the opportunity for hydrogen bonding from the side chain to the ring in several different ways was clearly apparent from the Dreiding models. To adequately immobilize the side chain the 7-hydroxyl was suspected of involvement. Although several sites were possible, the chelate formed by bonding the 7- to the 4-hydroxyl group looked ideal in the models.<sup>17</sup> This chelate ring contained seven atoms.<sup>17</sup>

Further information on the configuration of the side chain was now obtained by conformational analysis. From the coupling constants (Table I) the 6-H-7-H angle must be about 150° and the 5-H-6-H angle about 46 or 117°. The eight possible side-chain conforma-

(17) Hydrogen bonds vary in energy but are strongest when certain spatial requirements are met. The optimum OH-O distance in alcohols is about 2.74 Å and collinearity is desirable.<sup>18</sup> Thus, intramolecular hydrogen bonds lead to various-sized rings, but those containing five to seven atoms are common.

(18) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman and Co., San Francisco, Calif., 1960, Chapters 5 and 7; J. D. Bernal in "Hydrogen Bonding," D. Hadzi and H. W. Thompson, Ed., Pergamon Press Inc., New York, N. Y., 1959, p. 7.

tions allowed by these angle requirements were examined with the aid of Dreiding models and only that shown in IIa affords both the approximate required

angles and the possibility of hydrogen bonding from the 7-OH to the ring.<sup>19</sup> Thus, the analysis led to the conclusion that MTL was either IIa or its enantiomorph.

This structure, containing two *cis*-fused rings, both in the chain form, looked reasonable. The 8-methyl and 7-amino were both in the low-energy equatorial conformation. The foregoing reasoning was admittedly speculative at several points, but the results were completely confirmed and the D series was indicated by subsequent chemical degradations of MTL yielding D-galactose<sup>5</sup> from the pyranose portion, and D-allo-threonine<sup>5,21</sup> from the side-chain portion.

Reconstitution of the amide linkage yields III as the structure of lincomycin.

Resonance data obtained on some analogs and derivatives of MTL are collected in Table II. The glycoside configurations were determined from the nmr data. The spectrum (Figure 6) of 2-hydroxyethyl thiocelastaminide (HTC) (IV), the sugar portion of celesticetin,<sup>22</sup> was identical with that of MTL after allowing for the replacement of the S-methyl absorbance by the A<sub>2</sub>X<sub>2</sub> absorbance of the hydroxyethylthio substituent and the addition of a 7-methoxy signal,<sup>23</sup> thus confirming<sup>22</sup> that the sugar moieties of both antibiotics have the same configuration and showing that

(19) A second-choice structure had less desirable ring size and poorer agreement with observed angles but the same side-chain configuration as Ia. It had the 7-OH bonded to the ether oxygen to make a six-membered ring with an unusually long O—O distance. This model also required 5H—6H and 6H—7H angles to be 120° instead of 150 and 117° as observed. The rejection of this chelate was later confirmed when the 7-methoxy sugar was studied. It, too, showed the same hydrogen bonding; *vide infra*.<sup>20</sup>

(20) Since the exact location of the hydrogens in the hydrogen bond is not known, the structure is written in this noncommittal form. It may be possible that both hydrogens are involved in a diamond arrangement with the two oxygens.<sup>18</sup>

(22) H. Hoeksema, *J. Am. Chem. Soc.*, **86**, 4224 (1964).

(23) The 6-hydrogen of HTC absorbed 16 cps higher than that of MTL. This carbamino hydrogen could easily shift this much as a result of pH differences in these two solutions.

Figure 6. Nmr spectrum of  $\beta$ -hydroxyethyl thiocelastaminide in D<sub>2</sub>O.

HTC must be the  $\alpha$  anomer. The presence of a 7-methoxy group in HTC did not alter the chelation.

Compounds V, VI, VII, and VIII constitute two anomeric pairs of sugars and the glycoside configuration was deduced from the following observations.

- II, R<sub>1</sub> = R<sub>2</sub> = R<sub>3</sub> = H; R<sub>4</sub> = SCH<sub>3</sub>  
 IV, R<sub>1</sub> = CH<sub>3</sub>; R<sub>2</sub> = R<sub>3</sub> = H; R<sub>4</sub> = SCH<sub>2</sub>CH<sub>2</sub>OH  
 V, R<sub>1</sub> = R<sub>2</sub> = Ac; R<sub>3</sub> = SCH<sub>3</sub>; R<sub>4</sub> = H  
 VI, R<sub>1</sub> = R<sub>2</sub> = Ac; R<sub>3</sub> = H; R<sub>4</sub> = SCH<sub>3</sub>  
 VII, R<sub>1</sub> = R<sub>2</sub> = Ac; R<sub>3</sub> = OAc; R<sub>4</sub> = H  
 VIII, R<sub>1</sub> = R<sub>2</sub> = Ac; R<sub>3</sub> = H; R<sub>4</sub> = OAc  
 IX, R<sub>1</sub> = CH<sub>3</sub>; R<sub>2</sub> = Ac; R<sub>3</sub> = OAc; R<sub>4</sub> = H  
 X, R<sub>1</sub> = CH<sub>3</sub>; R<sub>2</sub> = Ac; R<sub>3</sub> = H; R<sub>4</sub> = SCH<sub>2</sub>CH<sub>2</sub>OAc

The nmr spectra, summarized in Table II of the  $\beta$  anomers of MTL-pentaacetate (V) and lincosamine hexaacetate (VII), differed from the  $\alpha$  anomers (VI and VIII) by showing 1-H resonances at lower frequency and *J*<sub>1,2</sub> couplings that were larger.<sup>24</sup> Since the 2-H in galactose is axial, the 1-H of the  $\beta$  isomer would be in a diaxial relationship to it, and this is in agreement with the 7.5- and 9-cps coupling constants.

Additional conclusions can be drawn from the 2-, 3-, and 5-H resonance frequencies. In the  $\alpha$  anomers, the axial S or O atom at 1 is nearer the symmetrically located axial hydrogens at 3 and 5 than it is in the  $\beta$  anomers. This deshielding effect of the O or S would be expected to increase the 3- and 5-H resonance frequency, and this was indeed observed as assigned. The differences were 20, 20, 34, and 17 cps. One would accordingly expect the 2-H to resonate at higher frequency in the  $\beta$  anomers since the O or S atom is now slightly closer than in the  $\alpha$  anomer. This was also observed on these pairs. The actual differences were 9 and 13 cps.

(24) In a study of the nmr of many pyranosides, Lemieux, *et al.*,<sup>25</sup> reported that in cases of rigid six-membered rings, equatorial hydrogens absorbed at a lower magnetic field (larger cps from TMS) than axial hydrogens did. Similar results have been observed in these laboratories. Further, it was noted that diaxial hydrogen neighbors showed a coupling constant of 5–10 cps and axial–equatorial or diequatorial hydrogen neighbors a coupling of 3–5 cps (the variation arises from some departure from perfect chair conformations<sup>19</sup>).

<sup>a</sup> II, IV, and XV were observed in D<sub>2</sub>O with SDSS reference, others were in CDCl<sub>3</sub> with TMS reference. <sup>b</sup> MTL, methyl thiolincosaminide; HTC, 2-hydroxyethyl thiocelosaminide. <sup>c</sup> Centers of absorbances located by spin-decoupling experiments. <sup>d</sup> Absorbances not factored completely, centers are approximated.

The celestosamine pentaacetate (IX) was judged to be β from the nmr data because of the very close similarity to that of β-lincosamine hexaacetate (VII) in all four of the above criteria. The fact that all the shifts and couplings in IX compared so closely to those of β-lincosamine hexaacetate (VII) confirms the conclusions that the two sugars are the same configuration and conformation.

The HTC pentaacetate sample X, when compared by nmr spectroscopy to the α- and β-MTL pentaacetates (VI and V), was judged to be the α anomer because of the high-frequency 1-H resonance, the small J<sub>1,2</sub>, the high-frequency 3- and 5-H resonance, and the low-frequency 2-H resonance. Since this compound came from celesticetin with no possible inversion at C-1, the celesticetin precursor must have been the α anomer.

Inspection of Table II reveals that the coupling constants of the 5-, 6-, and 7-hydrogens in the spectra of the acetylated sugars as a group were now quite different from those found in the MTL and HTC spectra. It is apparent that the esterification of the OH groups destroyed the chelate ring and as a result the side chain shifted to a second preferred orientation VIa. In

these acetylated molecules steric effects may well be the decisive factor. Catalin models indeed showed VI with the 5,6-hydrogens *trans* and the 6,7-hydrogens *gauche* to be a conformation with minimum steric interference among bulky acetyl groups.

**Analogs.** Many analogs of lincomycin have been studied by nmr. Extensive alterations of either the amino acid or sugar portions of lincomycin brought appropriate changes in the nmr spectrum. Minor modifications only altered the spectrum slightly. Thus, nmr served as a convenient tool for the identification of these analogs.

Alteration of the fermentation conditions and ingredients has produced several close analogs of lincomycin which were identified as XI–XIV.<sup>26</sup> When the R<sub>1</sub> substituent was hydrogen instead of methyl the N-

III, R<sub>1</sub> = CH<sub>3</sub>; R<sub>2</sub> = *n*-C<sub>3</sub>H<sub>7</sub>; R<sub>3</sub> = CH<sub>3</sub>

methyl singlet disappears from the spectrum and the new N-hydrogen appears with the exchangeable hydrogens. When R<sub>1</sub> was higher alkyl, the position and shape of the new absorptions from these alkyl groups were observed as expected.<sup>27</sup> The appropriate carbamine and terminal hydrogen frequencies are collected in Table III. It was noteworthy that the two methyls of

<sup>a</sup> D<sub>2</sub>O was the solvent. <sup>b</sup> Unusually broad.

the isopropyl group experience slightly different shielding. It is proposed that this arises from restricted rotation of this isopropyl group.

When the R<sub>2</sub> substituent was an alkyl group other than propyl, very little change was observed in the spectrum compared to that of lincomycin hydrochloride. The area of the methylene absorption and the characteristics of the terminal methyl absorption varied as expected<sup>27</sup> for these substituents.

When R<sub>2</sub> was hydrogen or ethoxy, the spectra lacked the methylene hump and the methyl triplet. The ethoxy analog showed instead a carbinol hydrogen quartet at 212 cps (*J* = 7 cps) or at 217 cps (*J* = 7 cps)

## V. Characteristic Absorptions of S-Alkyls of Lincomycin Hydrochloride<sup>a</sup>

substituent	Frequency, cps ( <i>J</i> , cps)		
	S-CH	C-CH <sub>3</sub>	Anomeric H
ethyl	128	...	322 (5.5)
isopropyl	158 (7.5)	75	327 (5.5)
isobutyl	178 (7.0)	78	331 (5.5)

<sup>a</sup> DMSO was the solvent.

is or *trans* configuration, and a methyl triplet and 72 cps, respectively. When the R<sub>2</sub> substituent was an alkyl group other than methyl, the spectrum showed minor changes. In the absence of the S-methyl singlet and appearance of appropriate S-alkyl absorptions were noted, together with a small shift in the absorption frequency of the anomeric hydrogen (see Table IV).

When the 7-hydroxyl was replaced by a chlorine atom XV, profound changes were observed in the carbinol region of the spectrum (see Table II). It is important to note that the intramolecular hydrogen bond is also destroyed and the *J*<sub>5,6</sub> and *J*<sub>6,7</sub> coupling constants indicate a side-chain conformation similar to VIa.

## Experimental Section

Nmr spectra were observed on a Varian A-60 spectrometer using solutions (ca. 0.4 ml, 0.3 *M*) of the samples in chloroform-*d* or deuterium oxide. Spectra were calibrated with internal tetramethylsilane (TMS) or sodium 2,2-dimethyl-2-silapentane-5-sulfonate (SDSS).<sup>9</sup> Spectra are calibrated in cps at 60 Mc to allow discussion of portions of multiplets.<sup>28</sup> Spin-decoupling experiments were performed with a Varian HR-100 spectrometer using a V-3521 integrator for field-sweep decoupling.<sup>18</sup>

The preparation of degradation products, derivatives, and analogs used in this study is described elsewhere.<sup>2,5-7,21,22,26</sup>

## Lincomycin. V. Amino Acid Fragment<sup>1</sup>

Barney J. Magerlein, Robert D. Birkenmeyer, Ross R. Herr, and Fred Kagan

Contribution from the Research Laboratories of the Upjohn Company, Kalamazoo, Michigan. Received December 20, 1966

**Abstract:** The amino acid derived from the cleavage of the antibiotic lincomycin is shown to be *trans*-1-methyl-4-*n*-propyl-L-proline. A partial synthesis of lincomycin is described.

Partial synthesis of the antibiotic lincomycin hydrochloride (1) into methyl thiolincosaminide (2) and 1-methyl-4-*n*-propyl-L-proline (3) was described in previous papers in this series.<sup>2,3</sup> The determination of the position of the *n*-propyl substituent and the configuration at carbon

presented at the 148th National Meeting of the American Chemical Society, Chicago, Ill., Sept 1964; Abstracts of Papers, p 6P. For a preliminary report cf. H. Hoeksema, B. Bannister, R. D. Birkenmeyer, and B. J. Magerlein, F. A. MacKellar, W. Schroeder, G. Slomp, R. Herr, *J. Am. Chem. Soc.*, **86**, 4223 (1964). R. Herr and G. Slomp, *J. Am. Chem. Soc.*, **89**, 2444 (1967). W. P. Schroeder, B. Bannister, and H. Hoeksema, *ibid.*, **89**, 2448

atoms C<sub>2</sub> and C<sub>4</sub> in the proline fragment is now reported.

The over-all plan was to establish the position of the alkyl group and confirm the absolute stereochemistry of C-2 by synthesis of 3-, 4-, and 5-*n*-propyl-1-methyl-L-proline<sup>4a</sup> and then to determine the absolute configuration of C<sub>4</sub> by degradation.

The synthesis of 1-carbobenzoxy-4-methylene-L-proline (5) resulting from the action of methylenetriphenylphosphorane on 1-carbobenzoxy-4-keto-L-proline (4) was recently described.<sup>4b</sup> Under similar conditions *n*-propylidenetriphenylphosphorane failed to give the desired 4-propylidene compound 6. However, a modification of the recently described sodium methylsulfinylcarbanion-dimethyl sulfoxide procedure<sup>5</sup> afforded 6 in 55% yield.

Although the double bond of 6 could be hydrogenated over a platinum catalyst to give 7, concomitant hydrogenation and hydrogenolysis of 6 to yield 8 was generally more convenient. Reductive methylation of 8 afforded the methylated amino acid 9 in high yield. The saturated amino acids 7, 8, and 9 were obtained as *cis-trans* isomers, but separation of these isomers could not be achieved through chromatography, electrophoresis, or fractional crystallization.

(4) (a) Rotational data suggested the L configuration for the carboxyl group. See ref 2. (b) M. Bethell, G. W. Kenner, and R. C. Sheppard, *Nature*, **194**, 864 (1962). The authors are indebted to Professor G. W. Kenner for experimental details of this reaction prior to publication.

(5) R. Greenwald, M. Chaykovsky, and E. J. Corey, *J. Org. Chem.*, **28**, 1128 (1963).

Conversion of the acids **9** to the amides afforded a mixture of *cis* and *trans* isomers **10** and **11** which was readily separated by chromatography over silica gel. One of these compounds was identical with the amide prepared from naturally occurring propylhygric acid, thus establishing the position of the propyl group at C-4 and the absolute configuration of the C-2 carbon atom as L. The absolute configuration of C-4 was established by degradation.

The amino acid fragment obtained from the hydrazinolysis of lincomycin was frequently partially or completely epimerized at the  $\alpha$ -carbon atom. After conversion to the amides, the D and L isomers, **10** and **12**, were separated by chromatography.

The nmr curves of diastereoisomers **10** and **11** (epimeric at the 4 position) differed from each other as did the curves of **10** and **12**. However, the curves of the mirror images **11** and **12** were identical as were those for **10** prepared from either synthetic amino acids **9** or natural amino acid **3**. Since the amides **10** prepared from either epimeric acids obtained by hydrazinolysis of lincomycin or from synthesis were identical, and since the synthetic amide was prepared from 4-keto-L-proline, we concluded that the *n*-propyl group was at position 4 and that the amino acid was in the L configuration. The isomers **11** and **12** which possessed identical nmr spectra, but optical rotations of opposite sign, were formulated as optical isomers though the absolute configuration of the propyl group was not as yet established. The absolute configuration of the

*n*-propyl group was determined by degradation as will be described later.

Concurrently with the synthesis of 1-methyl-4-*n*-propyl-L-proline from 1-carbobenzoxy-4-keto-L-proline, total syntheses of this amino acid and 1-methyl 3-*n*-propylproline were investigated. The method of synthesis was similar to that published for racemic 4-methylproline.<sup>6</sup> Acetamidomalonic ester (**13**) was condensed with the appropriate aldehyde **14** or **15** to yield the cyclic intermediate **16** or **17**. This compound was not obtained pure, but was reduced and hydrolyzed to **18** or **19**. Reductive methylation of **18** and **19** gave racemic **20** and **21**. In neither case was racemic 3-*n*-propyl or 4-*n*-propyl-1-methylproline resolved though thin layer chromatography of the amide derivatives indicated that the *cis* and *trans* *dl* pairs could be separated by chromatography. The 4-substituted amides prepared from **21** showed two spots on thin layer chromatography which moved with the racemic acids obtained from lincomycin (**10** and **12**) and which separated from the 3-substituted amides prepared from **20**. This constituted additional evidence for 4 substitution in the hygric acid moiety of lincomycin.

The racemic acid **21** was coupled with the amine **2** using the mixed carbonic anhydride method. The crude product showed 12% of the activity of lincomycin when assayed microbiologically or by thin layer chromatography. No attempt was made to purify this material.

Under similar conditions racemic 1-methyl-3-*n*-propylproline (**20**) failed to condense with **2**, only the carbamate **22** being isolated from the reaction mixture.

**22**

(6) J. S. Dalby, G. W. Kenner, and R. C. Sheppard, *J. Chem. Soc.*, 4387 (1962).

ic 1-methyl-5-*n*-propylproline was synthesized and separated into the racemic pairs 23

spectra of 23 and 24 differed sufficiently from the natural amino acid so as to exclude the 5-*n*-propylprolines (23 and 24) as lincomycin ion products.

tereochemistry at C-4 in 1-methyl-4-*n*-propyl- was determined by the use of a degradative introduced by Neuberger in his classical work stereochemistry of hydroxyproline.<sup>7</sup> This was recently employed in the determination of lute configuration of the 4-methyl group in 4-roline (25 and 26).<sup>8</sup> In this case the oxidation iastereoisomers 25 and 26 gave D-(+)-methyl- acid (27). Exhaustive oxidation of the racemino acid fragment (3') from lincomycin D-(+)-*n*-propylsuccinic acid (28).<sup>9</sup>

stereorelationship between D-(+)-methyl and propylsuccinic acid is known,<sup>10</sup> we concluded propyl group of 3 is oriented similarly to the group of 25 and 26. That is, it is *trans* to the yl. Therefore, the amino acid fragment from in is *trans*-1-methyl-4-*n*-propyl-L-proline (29).

Two partial syntheses of lincomycin (1) from 4-hydroxy-L-proline were achieved. In the first the *cis-trans* mixture of 1-methyl-4-*n*-propyl-L-proline (9) was coupled with methyl thiolincosaminide (2) to give a mixture of lincomycin (1) and its *cis* isomer 33. In the first step of the second method, 1-carbobenzoxy-4-propylidene-L-proline (6) was hydrogenated to give 7, a *cis* and *trans* mixture. The hydrogenation of the exocyclic double bond in 1-carbobenzoxy-4-propylidene-L-proline (6) over platinum oxide or platinum or palladium on the usual supports led to mixtures containing only a small percentage of the desired *trans* isomer. The palladium catalysts invariably also caused hydrogenolysis of the carbobenzoxy group. The high ratio of the *cis* isomer indicated that the hydrogen atoms were approaching the molecule from the side opposite the carboxyl group. Therefore, if the amino acid could be attracted to the catalyst by its carboxyl group, the hydrogen atoms should then approach from the carboxyl side forming a greater proportion of *trans* isomer. Such a situation may exist if the catalyst were deposited on a basic ion-exchange resin. Therefore, the use of platinum on an ion-exchange resin<sup>11</sup> was investigated and the hydrogenation product found to contain considerably more of the desired *trans* isomer of 7 (25–35%) in which the carbobenzoxy group remained intact.

The blocked amino acid 7 was coupled with methyl thiolincosaminide (2) in high yield, forming 31. The blocking group was removed by hydrogenolysis and the resulting product 32 reductively methylated to yield a mixture of lincomycin (1) and its *cis* isomer 33. From this mixture pure lincomycin (1) was isolated by chromatography. This material was identical in both its physical and microbiological properties with the natural antibiotic. The *cis* isomer 33 was also isolated as a pure compound. It possessed about one-half the antibacterial activity of lincomycin. This semisynthetic

(11) F. J. McQuillin, W. O. Ord, and P. L. Simpson, *J. Chem. Soc.*, 5996 (1963).

preparation of lincomycin confirmed the structure of the amino acid portion of lincomycin.

The partial synthesis of lincomycin from 4-hydroxy-L-proline has been adapted to the preparation of lincomycin analogs having variations in both the amino acid and sugar moieties.<sup>12</sup>

## Experimental Section<sup>13</sup>

**1-Carbobenzoxy-4-propylidene-L-proline Dicyclohexylamine Salt (6).** A sodium hydride suspension (3.8 g) was warmed with 75 ml of dimethyl sulfoxide at 70–75° until reaction was completed. After cooling to 20°, 30.8 g of propyltriphenylphosphonium bromide was added. The resulting red solution was stirred for 30 min to ensure complete reaction. A solution of 5.2 g of 4<sup>14</sup> in 15 ml of dimethyl sulfoxide was added over a period of 15 min. The resulting mixture was stirred for 20 min at 26° and then at 70° for 4 hr. The cooled reaction mixture was treated with 100 ml of 5% potassium bicarbonate and 100 ml of water and filtered. The filtrate was washed twice with 150-ml portions of ether and the ether discarded after back-extracting with bicarbonate solution. The aqueous solution was diluted with 200 ml of water, acidified, and extracted with three 200-ml portions of ether. The combined ether solution was washed with three 50-ml portions of saturated sodium bisulfite solution, then with water, and dried. The residue, 5.7 g, obtained after evaporation of the solvent, was dissolved in 18 ml of acetonitrile and treated with 2.8 ml of dicyclohexylamine. The crystalline salt, 5.2 g (55% yield), melted at 154–157°. The analytical sample prepared by three recrystallizations from acetonitrile melted at 164–166° and showed  $[\alpha]_D - 8^\circ$  (chloroform).

*Anal.* Calcd for C<sub>25</sub>H<sub>42</sub>N<sub>2</sub>O<sub>4</sub>: C, 71.45; H, 9.00; N, 5.95. Found: C, 71.77; H, 9.39; N, 5.91.

**trans- and cis-4-n-Propyl-L-proline (8).** Ten grams of 6 was converted to the free base as described below in the preparation of 30.

This oil was dissolved in 250 ml of methanol and shaken under hydrogen over 2 g of platinum on Dowex<sup>11</sup> for 4 hr. Palladium on carbon (2 g, 10%) was added and shaking continued for 2 hr. The catalyst was removed by filtration and the solvent distilled under reduced pressure. The residue was shaken with ether and 2.77 g (82.9%) of crystalline 8, mp 220–223° dec, deposited. Three recrystallizations from methanol–acetone afforded the analytical sample, mp 232–234°,  $[\alpha]_D - 63^\circ$  (water).

*Anal.* Calcd for C<sub>8</sub>H<sub>13</sub>NO<sub>2</sub>: C, 61.12; H, 9.26; N, 8.91. Found: C, 61.06; H, 9.46; N, 8.94.

**trans- and cis-1-Methyl-4-n-propyl-L-proline Hydrochloride (9).** Formalin (4 ml) was added to 3.4 g of crude 8 from the previous step dissolved in 200 ml of methanol. The mixture was shaken under hydrogen for 2.5 hr at 45 psi pressure. The catalyst was removed by filtration and the solvent distilled. The residue was crystallized from methanol–ether–hydrogen chloride to afford 2.82 g of 9, mp 200–202°. After several recrystallizations from methanol–ether the hydrochloride melted at 201–206° and gave  $[\alpha] - 60^\circ$  (water).

*Anal.* Calcd for C<sub>9</sub>H<sub>15</sub>NO<sub>2</sub>Cl: C, 52.04; H, 8.73; N, 6.75. Found: C, 51.72; H, 8.96; N, 6.44.

**cis-Lincomycin Hydrochloride (33).** A mixture of 2.47 g of 9 and 7.6 ml of *n*-tributylamine in 80 cc of distilled acetonitrile was stirred until all of the solid had dissolved. The solution was cooled in an ice bath and 1.64 g of isobutyl chloroformate slowly added. A solution of 3.0 g of methyl thiolincosaminide in 40 ml of water was added. The reaction mixture was stirred for 1 hr in the ice bath and 3 hr at 26°. The acetonitrile was distilled under vacuum. The residue was diluted with 20 ml of water and extracted twice with ether. The aqueous solution was lyophilized. The residue was triturated several times with chloroform and this solution chromatographed over Florisil,<sup>15</sup> using an elution system of Skellysolve B<sup>16</sup>–ethyl

acetate with increasing amounts of methanol. The fractions which showed material in the lincomycin area by tlc were combined. This oil (0.86 g) was dissolved in dilute hydrochloric acid and the crude hydrochlorides 33 and 1 precipitated with acetone. The yield was 480 mg (9.04%). Tlc (ethyl acetate–acetone–water, 8:5:1) showed a major spot moving slightly slower than lincomycin and also a weak lincomycin spot. Bioassay indicated 37% lincomycin. Bioautography showed activity in the lincomycin area.

Several recrystallizations of the crude hydrochloride afforded an analytical sample, mp 147–150°, of *cis*-lincomycin hydrochloride (33) containing only a trace of lincomycin.

*Anal.* Calcd for C<sub>18</sub>H<sub>25</sub>ClN<sub>2</sub>O<sub>6</sub>S: C, 48.80; H, 7.96; N, 6.32. Found (corrected for 9.47% H<sub>2</sub>O): C, 49.15; H, 7.80; N, 6.39.

**cis-1-Methyl-4-n-propyl-L-proline Amide (11) and trans-1-Methyl-4-n-propyl-L-proline Amide (10).** A mixture of 3.09 g of 9, 9.5 ml of tri-*n*-butylamine, 100 ml of acetonitrile, and 40 ml of acetone was stirred until solution was complete. To this solution, cooled to 10°, there was added 2.05 ml of isobutyl chloroformate. The reaction mixture was stirred for 30 min in an ice bath after which time 15 ml of ammonium hydroxide was added. Stirring was continued for 2 hr. The solvent was distilled under vacuum. The residue was acidified and extracted with ether. After neutralizing the aqueous solution, it was extracted with methylene chloride. Chromatography of this product over silica gel<sup>17</sup> using 80% aqueous acetone as the eluent gave two fractions, one showing an enrichment of 10, the other almost pure 11. The 10 component-rich fraction (359 mg) was rechromatographed to yield a small fraction of fairly pure 10, the other fractions being mixtures of 10 and 11. The latter fractions were again rechromatographed and the resulting fractions recombined on the basis of tlc. The fractions containing the purest 10 were combined and recrystallized from Skellysolve B to give 10 mg of 10, estimated to be about 85% pure on the basis of tlc. This material showed  $[\alpha]_D - 93^\circ$  (water). Its nmr was almost identical with 10 isolated from natural 4-propylhygric acid.

In another experiment the original crystalline product was recrystallized for analysis from ethyl acetate–Skellysolve B. Tlc showed it to be almost pure 11, mp 113.5–115.5°,  $[\alpha]_D - 104^\circ$  (water).

*Anal.* Calcd for C<sub>9</sub>H<sub>15</sub>O<sub>2</sub>N: C, 63.49; H, 10.66; N, 16.46. Found: C, 63.41; H, 10.76; N, 16.28.

**trans-1-Methyl-4-n-propyl-L-proline Amide (10) and cis-1-Methyl-4-n-propyl-D-proline Amide (12) from Hydrazinolysis Cleavage Product.** Partially racemic 1-methyl-4-n-propylproline was converted to the mixture of isomeric amides in the same manner as described for the preparation of racemic 1-methyl-3-n-propylproline amide. Recrystallization of the crude product from Skellysolve B gave a 65% yield of material, mp 86–86.5°,  $[\alpha]_D + 10^\circ$  (water).

*Anal.* Calcd for C<sub>9</sub>H<sub>15</sub>NO<sub>2</sub>: C, 63.49; H, 10.66; N, 16.46. Found: C, 63.35; H, 10.92; N, 16.28.

A thin layer chromatograph of the above material on silica gel, using an acetone–water (8:2) irrigating system, disclosed the presence of two compounds of very similar mobility. Separation was effected *via* chromatography over silica gel using acetone–water (8:2) for elution. The faster moving component was identified as the *L-trans* amide and melted at 117–118° after recrystallization from Skellysolve B;  $[\alpha]_D - 93^\circ$  (water).

*Anal.* Calcd for C<sub>9</sub>H<sub>15</sub>NO<sub>2</sub>: C, 63.49; H, 10.66; N, 16.46. Found: C, 63.57; H, 10.73; N, 16.71.

The more polar component, the *D-cis* amide,  $[\alpha]_D + 103^\circ$  (water), melted at 114–115° after recrystallization from Skellysolve B.

**1-Acetoxy-2,2-carbethoxy-4-propyl-5-hydroxypyrrolidine (17).** A mixture of 5.6 g of 2-propylacrolein (15),<sup>18</sup> 10 g of diethyl acetamidomalonate, and 0.25 ml of 26% sodium methoxide–methanol solution in 150 ml of benzene was stirred for 3 hr at ambient temperature. The solution was neutralized with a few drops of acetic acid, clarified by filtration, and evaporated. This material did not crystallize and was used in the following step.

**Racemic 4-n-Propylproline Hydrochloride (19).** The pyrrolidine 17 from above was suspended in 127 ml of water and 127 ml of concentrated hydrochloric acid, and 22.8 g of granulated tin added.

xing for 1 hr, the metal was removed by filtration and the evaporated under vacuum. The solution was saturated with hydrogen sulfide, and the precipitated solids were separated. The solution was treated repeatedly in this manner. The reaction mixture was lyophilized. The residue was dissolved in a small amount of water, extracted with ether, and again lyophilized. It was dried at 55° under vacuum. The residue, 14.7 g, was dried from acetonitrile affording 1.62 g of 19, mp 162–165°. Recrystallizations from methanol–ether of material prepared in a similar manner afforded an analytical sample, mp 165–

Calcd for  $C_8H_{13}NO_2 \cdot HCl$ : C, 49.61; H, 8.33; N, 7.53. Found: C, 49.24; H, 8.13; N, 7.53.

**1-Methyl-4-propylproline Hydrochloride (21).** In the manner described for the preparation of 20, 1.1 g of 19 was methylated with 620 mg of 21, mp 164–166°. Recrystallization from ether gave an analytical sample, mp 165–167°.

Calcd for  $C_9H_{17}NO_2 \cdot HCl$ : C, 52.04; H, 8.73; N, 7.13. Found: C, 51.74; H, 8.48; N, 7.13.

**1-Methyl-4-n-propylprolylamide.** In the manner described for the preparation of 10 and 12, 1.0 g of 21 was converted to the corresponding amide, mp 86–89°, in 90% yield. An analytical sample prepared from Skellysolve B melted at 84–85°.

Calcd for  $C_9H_{19}NO_2$ : C, 63.49; H, 10.66; N, 16.46. Found: C, 63.53; H, 10.64; N, 16.48.

**Lincomycin.** In the manner described for the preparation of 16, racemic 21 was condensed with methyl thiolincosaminide to give a crude product which possessed 11% of the antibacterial activity of lincomycin and showed about the same amount of lincomycin layer chromatography.

**2-Oxy-2,2-carbethoxy-3-propyl-5-hydroxypyrrolidine (16).** In the manner described above, 2-hexenal<sup>19</sup> (14) and diethyl acetonate were condensed to afford 16, mp 101–102°, in a 1:1 ratio after recrystallization from acetone–ether.

Calcd for  $C_{13}H_{22}NO_6$ : C, 57.13; H, 7.99; N, 4.44. Found: C, 57.07; H, 8.02; N, 4.72.

**3-n-Propylproline Hydrochloride (18·HCl).** Acidic chloride 16, as described in the preparation of 17, afforded 18, mp 165–168°, after recrystallization from ether.

Calcd for  $C_8H_{13}ClNO_2$ : C, 49.61; H, 8.33; N, 7.23; Cl, 18.09. Found: C, 49.84; H, 8.30; N, 7.49; Cl, 18.09.

**3-n-Propylproline (18).** A mixture of 880 mg of 3-n-propylproline hydrochloride (18·HCl), 2.0 g of silver carbonate, and 10 ml of water was stirred at 25° for 0.5 hr and then warmed on a water bath for 30 min and filtered. The filtrate was evaporated under vacuum and the residue recrystallized from ethanol–ethyl ether to give 18, mp 229–230°. The yield of once recrystallized 18 was 600 mg (85% yield).

Calcd for  $C_8H_{13}NO_2$ : C, 61.12; H, 9.62; N, 8.91. Found: C, 61.45; H, 9.60; N, 8.95.

**1-Methyl-3-n-propylproline (20).** A mixture of 14 g of 3-n-propylproline (18), 11.8 ml of formaldehyde, 200 ml of water, and 2.0 g of 10% Pd–C catalyst was hydrogenated on a hydrogenator at 35 psi hydrogen pressure. A yield of 11.6 g of product was obtained, melting at 202–203°, after recrystallization from ethanol–ethyl acetate.

Calcd for  $C_9H_{17}NO_2$ : C, 63.12; H, 10.01; N, 8.18. Found: C, 63.02; H, 10.02; N, 8.42.

**1-Methyl-3-n-propylprolylamide.** To a stirred mixture of racemic 1-methyl-3-n-propylproline (20), 1.68 ml of triethylamine, and 69 ml of dry acetonitrile at 0° was added 0.58 g of ethyl chloroformate. The reaction mixture was maintained at 0° for 0.5 hr and 6 ml of concentrated  $NH_4OH$  then added. After stirring 18 hr at 25°, the reaction mixture was evaporated under vacuum and the residue dissolved in 50 ml of water, with HCl, and extracted with four 50-ml portions of ether. The methylene chloride extracts were dried with anhydrous sodium sulfate and the aqueous phase was neutralized and extracted with four 50-ml portions of methylene chloride. The methylene chloride extracts were combined and evaporated and the residue was recrystallized from Skellysolve B to a melting point of 99–100°. A 60% yield of product was obtained.

Calcd for  $C_9H_{19}N_2O_2$ : C, 63.49; H, 10.66; N, 16.46. Found: C, 63.60; H, 10.85; N, 16.22.

Material showed only one spot when chromatographed on

silica gel using a methyl ethyl ketone–acetone–water system (75:25:10).

**Attempted Coupling of Racemic 1-Methyl-3-n-propylproline (20) with Methyl Thiolincosaminide.** To a mixture of 60 ml of distilled acetonitrile, 1.68 ml of triethylamine, and 1.03 g of amino acid 20 cooled at 0° was added 0.87 ml of isobutyl chloroformate. After stirring at 0° for 0.5 hr, 1.52 g of methyl thiolincosaminide dissolved in 20 ml of water was added. Stirring was continued for a period of 60 hr at 25°. The reaction mixture was evaporated to dryness and the residue chromatographed over silica gel, eluting with acetone. The fast-moving material was isolated (140 mg) and recrystallized from acetone–Skellysolve B to a melting point of 186–187°. The infrared and nmr data support the carbamate structure 22.

Anal. Calcd for  $C_{14}H_{27}NO_7$ : C, 47.57; H, 7.70; N, 3.96; O, 9.07. Found: C, 47.73; H, 7.84; N, 4.03; O, 9.25.

**Ethyl 2,5-Dibromooctanoate (35).** At 0° 13 g of 5-caprylo-lactone (34) was added to 10.5 ml of phosphorus tribromide followed by 7.1 ml of bromine. After stirring at ambient temperature for 18 hr, 1 ml of phosphorus tribromide and 6 ml of bromine were added. The reaction mixture was heated at reflux for 24 hr. To the cooled solution was added 30 ml of absolute ethanol and the mixture heated at reflux for 1.5 hr. The solvents were removed under vacuum and the residue was dissolved in benzene. This solution was washed free of bromide ion, dried, and concentrated. The yield of 35, bp 125–135° (0.8 mm), was 15–20 g (43–57% yield).

Anal. Calcd for  $C_{10}H_{18}Br_2O_2$ : C, 36.38; H, 5.49; Br, 48.43; O, 9.70. Found: C, 35.43; H, 5.37; Br, 48.75; O, 9.81.

**Racemic 1-Methyl-5-n-propylproline N-Methylamides (36).** A 14.85-g quantity of ethyl 2,5-dibromooctanoate (35) was condensed with 17.4 g of methylamine in 85 ml of methanol by heating at 140° for 4 hr in an autoclave. The reaction mixture was filtered and evaporated *in vacuo* to dryness. The residue was dissolved in chloroform and filtered to remove methylamine hydrobromide. The filtrate was evaporated to dryness, and the residue was distributed countercurrently for 200 transfers using the solvent system ethyl acetate–ethanol–cyclohexane–water (1:1:1:1). Two main peaks were noted on analysis by determination of solids. The first, in tubes 80–107, was pooled and evaporated to dryness. The partially crystalline residue was recrystallized from Skellysolve B to give 1.8 g of product.

Anal. Calcd for  $C_{10}H_{20}N_2O$ : C, 65.18; H, 10.94; N, 15.21. Found: C, 65.86; H, 11.27; N, 14.54.

The second peak in tubes 118–150 was pooled and evaporated to dryness. The residue crystallized in the refrigerator, but melted at room temperature. No suitable solvent for recrystallization was found, so this material was used directly in the next step.

**cis- and trans-1-Methyl-5-n-propylproline Hydrochloride (23 and 24).** A 250-mg sample of the crystalline methylamide of 1-methyl-5-n-propylproline (36) was heated at reflux with 10 ml of 6 N HCl for 4 hr. The solution was evaporated to dryness *in vacuo*. The residue was dissolved in water and Dowex 2 ( $OH^-$ ) was added to about pH 10. The resin was collected and eluted with dilute hydrochloric acid. The eluate was evaporated to dryness, and the residue was dissolved in a small amount of anhydrous ethanol. Ether was added until the solution was cloudy, and the mixture was cooled. A small amount of yellow oil separated. The supernatant was decanted and diluted with several volumes of ether. Crystals formed slowly on cooling. From two such runs, 143 mg of crystalline material was obtained. Recrystallization from acetonitrile–ether gave 95 mg of hydrochloride.

Anal. Calcd for  $C_9H_{18}ClNO_2$ : C, 52.04; H, 8.73; N, 6.74; O, 15.41; Cl, 17.07. Found: C, 51.12; H, 8.45; N, 7.03; O, 14.85; Cl, 16.55.

About 800 mg of the lower melting isomer was hydrolyzed by heating under reflux with 40 ml of 6 N HCl for 4 hr. The product was isolated as described above to give 107 mg of recrystallized amino acid hydrochloride.

Anal. Found: C, 51.82; H, 9.33; N, 7.08; O, 18.5; Cl, 16.90.

**D-(+)-n-Propylsuccinic Acid (27) from Oxidation of Partially Racemic 1-Methyl-4-n-propylproline.** A solution of 7.44 g of partially racemized 1-methyl-4-n-propylproline hydrochloride in 100 ml of water containing 36 ml of 1 N sodium hydroxide was added slowly with vigorous stirring to 28 g of potassium permanganate in 550 ml of water. The temperature of the mixture was maintained at  $25 \pm 2^\circ$  by occasional cooling. When most of the acid was added the permanganate color was no longer present. Therefore, 2 g of the additional permanganate was added. The reaction mixture was filtered after the addition of filter aid. The purple color of the filtrate was discharged with excess sodium bisulfite and

the solution refiltered. The clear filtrate was acidified and lyophilized. The residue from lyophilization was shaken with absolute alcohol-ether (3:1) and filtered. The filtrate was evaporated to yield 4.4 g of oil. This oil was chromatographed over 125 g of silica gel using a mixture of solvents for elution made up of benzene-methanol-acetic acid (10:2:1). The fractions thus obtained were checked by thin layer chromatography (same system) using *dl*-propylsuccinic acid<sup>30</sup> as the control. Those fractions showing only material moving with the control were combined (1.83 g) and crystallized from benzene-Skellysolve B several times. The crystalline product, 280 mg, melted at 101.5–103.5° and rotated at +23° (water).

*Anal.* Calcd for  $C_{17}H_{23}O_4$ : C, 52.49; H, 7.55. Found: C, 52.48; H, 7.67.

*cis*- and *trans*-1-Carbobenzoxy-4-*n*-propyl-L-proline (30). The amine salt (6, 10 g) was shaken with ether and 2% potassium hydroxide. The aqueous layer was separated and acidified. Extraction with methylene chloride led to the isolation of 6 g of oily acid. A mixture of 2 g of this oil and 800 mg of platinum on Dowex-1 catalyst<sup>30</sup> in 50 ml of methanol was shaken under 40 psi hydrogen pressure for 17 hr. The catalyst was removed by filtration and the solvent distilled *in vacuo*, leaving a residue of 2 g of oily 30. Thin layer chromatography, using a methanol-5% ammonium hydroxide system and permanganate-periodate indicator spray, indicated that the double bond was hydrogenated. Ninhydrin gave a negative test. This product resisted crystallization and was used without purification in the next step.

*cis*- and *trans*-Methyl N-(1'-Carbobenzoxy-4'-*n*-propyl-L-prolyl)-thiolincosaminide (31). To a solution of 7.5 g of 30 and 4.25 ml of triethylamine in 700 ml of distilled acetonitrile cooled to 0° there was added 4.16 ml of isobutyl chloroformate in 5 ml of acetonitrile. The mixture was stirred at 0° ( $\pm 5^\circ$ ) for 15 min. A solution of 7 g of methyl thiolincosaminide (2) in 100 ml of water was added rapidly. The resulting solution was stirred at 0° for 1 hr, the cooling bath removed, and stirring continued for another hour. The acetonitrile was removed by distillation under vacuum leaving a partially crystalline residue. The mixture was cooled to 10° and filtered. After drying at 55° under vacuum the crystalline product weighed 10.5 g and melted at 191–194°. *In vitro* assay *vs. S. lutea* showed <1% the antibacterial activity of lincomycin. This

material was recrystallized twice from ethyl acetate containing a few drops of water to afford the analytical sample, mp 197–203°,  $[\alpha]_D +111^\circ$  (MeOH).

*Anal.* Calcd for  $C_{23}H_{33}N_2O_5S$ : C, 57.01; H, 7.27; N, 5.32; S, 6.09. Found: C, 56.93; H, 7.45; N, 5.35; S, 6.03.

*cis*- and *trans*-Methyl N-(4-Propyl-L-prolyl)thiolincosaminide Hydrochloride (32·HCl). A solution of 8.95 g of 31 in 200 ml of methanol was shaken over 2 g of 10% Pd-C under 40 psi hydrogen pressure for 6 hr. The catalyst was removed by filtration and the solution concentrated under vacuum. The residue was dissolved in 75 ml of 0.5 N hydrochloric acid and 250 ml of water with warming to about 35°. Dilution with 1500 ml of acetone precipitated 32·HCl which was collected by filtration. The crystals, dried at 55° under vacuum, weighed 6.0 g (82.3% yield) and melted at 202–205°. The rotation was +151° (H<sub>2</sub>O).

*Anal.* Calcd for  $C_{17}H_{23}N_2O_5S \cdot HCl$ : C, 47.57; H, 7.75; N, 6.57; S, 7.47. Found (corrected for 3.31% water): C, 47.67; H, 7.72; N, 6.53; S, 7.14.

In one experiment the free base crystallized from acetone. It melted at 178–180°.

*Anal.* Calcd for  $C_{17}H_{23}N_2O_5S$ : C, 52.02; H, 8.22; N, 7.14. Found: C, 51.97; H, 8.01; N, 7.00.

**Lincomycin Hydrochloride (1) and *cis*-Lincomycin Hydrochloride (33).** Two grams of 32·HCl, 2.4 ml of formalin, and 800 mg of 10% palladium on carbon in 200 ml of methanol was shaken under 40 psi hydrogen pressure for 5 hr. The catalyst was removed by filtration. Triethylamine (1 ml) was added and the solution evaporated. The residue was chromatographed twice over silica gel using for elution a solvent mixture of ethyl acetate-acetone-water (8:5:1). The various fractions were monitored by thin layer chromatography on silica gel using the same solvent system and fractions showing only 1 and 33 combined. The crude 1 (free base) fraction weighed 320 mg. It was dissolved in dilute hydrochloric acid and 1·HCl precipitated by the addition of acetone. The yield of 1·HCl was 290 mg. After two recrystallizations from the same solvent it melted at 155–157° dec. This material had identical spectra with lincomycin hydrochloride by infrared and nmr. It possessed full antibacterial activity when compared with lincomycin hydrochloride.

The slower moving fraction, 570 mg, from above was similarly converted to its hydrochloride. After recrystallization from acetone-water it melted at 138–145° dec and was identical in the infrared and nmr with *cis*-lincomycin hydrochloride (33) prepared as described above.

## The Morphine-Thebaine Group of Alkaloids. IX.<sup>1</sup> The Reaction of Thebaine with Magnesium Iodide

K. W. Bentley

*Contribution from The Research Laboratories, Reckitt and Sons Ltd., Kingston-upon-Hull, England. Received September 26, 1966*

**Abstract:** The reaction of thebaine with anhydrous magnesium iodide has been shown to give the iminium salt VIII, the structure of which has been deduced from its oxidation to 4-methoxyphthalic acid, its hydrolysis and cyclodehydration to thebenine (II), and its reduction to neodihydrothebaine (VII, R = H). The structure of neodihydrothebaine has been confirmed by degradation and spectral studies. Hydrolysis and recyclization of the iminium salt VIII has been found to give an enamine, kryptothebaine, which is clearly not the enamine I and is assigned structure IV.

The reaction of thebaine (III) with anhydrous magnesium iodide in ether and benzene has previously been shown<sup>2</sup> to give a product containing magnesium

(1) Part VII: K. W. Bentley, J. C. Ball, and J. P. Ringe, *J. Chem. Soc.*, 1963 (1956); the paper by K. W. Bentley and S. F. Dyke, *ibid.*, 2574 (1959), is now regarded as part VIII of this series.

(2) K. W. Bentley and R. Robinson, *ibid.*, 947 (1952).

and iodine, to which the iminium salt structure VIII was assigned on the basis of its conversion into phenyldihydrothebaine (VII, R = Ph) on treatment with phenylmagnesium bromide. This assignment of structure is now supported by the reduction of the salt to neodihydrothebaine (VII, R = H), by its oxidation to 4-

methoxyphthalic acid (IX),<sup>3</sup> and by its conversion into thebenine (II).

(3) In an earlier report of this reaction,<sup>2</sup> it was stated that 4-methoxyphthalic acid could not be isolated from the products of the oxidation under the conditions used for the oxidation of phenyldihydrothebaine. This acid has now been isolated after oxidation of the iminium salt with very much larger quantities of permanganate than previously used, and it seems probable that in the earlier work oxidation was incomplete probably not progressing even to the production of a homophthalic acid.

Reduction of the iminium salt VIII with lithium aluminum hydride in ether or with sodium borohydride in ethanol takes place very rapidly and affords a very good yield of (+)-neodihydrothebaine (VII, R = H);<sup>4</sup> the

(4) This reaction was previously reported<sup>3</sup> to give a noncrystalline uncharacterizable product. It is now known that the lithium aluminum hydride used in the earlier work was seriously contaminated with aluminum chloride, which is known to affect the course of reductions with

mild conditions involved in the formation and reduction of the salt were insufficient to cause racemization of the diphenyl system, which is generated in one configuration only. The structure assigned to neodihydrothebaine (VII, R = H) has been confirmed by degradation of the base and its methyl ether. Hofmann degradation of neodihydrothebaine methiodide occurs readily in aqueous potassium hydroxide to give the isomethine XI (R = H) only, the structure of the product being demonstrated by its easy cyclization to the nonphenolic base XII on heating with concentrated hydrochloric acid. The phenolic nucleus apparently inhibits Hofmann degradation on one side of the nitrogen since only the isomethine XI (R = H) is produced during this reaction, and the methiodide of the isomethine is resistant to further degradation in refluxing 40% aqueous potassium hydroxide. By contrast, however, the isomethine methyl ether (XI, R = Me) methiodide can be degraded in aqueous solution to a neutral product, which is presumably the olefin XVIII (Et = CH=CH<sub>2</sub>), but which could not be adequately characterized owing to the speed with which it polymerized. Catalytic reduction of the isomethine XI (R = H) proceeded very rapidly and gave the dihydro base XV (R = H). The methiodide of this base, like that of the parent phenol XI (R = H) resists further Hofmann degradation in aqueous solution, though the methiodide of the methyl ether XV (R = Me) can be easily degraded to the olefin XVIII.

Hofmann degradation of neodihydrothebaine methyl ether methiodide, unlike the degradation of the parent phenol, affords a mixture of two products, readily separated as the methiodides. The minor component is identical with the isomethine methyl ether (XI, R = Me) and hence the major product, which is isomeric with this base, may be assigned the structure X of the methine base. Evidently in the absence of the stabilizing effect of the phenolic hydroxyl degradation can occur with ring fission on either side of the nitrogen atom.<sup>5</sup> Oxidation of the mixture of methine and isomethine bases obtained in this way with alkaline potassium permanganate afforded an uncrystallizable yellow acid, which is presumably a mixture of  $\alpha$ -keto acids since on further oxidation with alkaline hydrogen peroxide it gave a good yield of 5,6,5'-trimethoxydiphenic acid (XIII), identical with material prepared from phenyldihydrothebaine (VII, R = Ph) and from acetylthebaol. The structure of this acid was further confirmed by its cyclization to 1,5,6-trimethoxyfluorenone-4-carboxylic acid.

this reagent. It may be noted that the characteristics of the reduction product described in the earlier communication bear a striking resemblance to those of the product of reduction of kryptothebaine (IV) reported in this paper.

(5) A similar difference in behavior on Hofmann degradation has been observed between methylidihydrothebaine (VII, R = Me) and its O-acetyl derivative [L. F. Small and E. M. Fry, *J. Org. Chem.*, **3**, 509 (1939)], and between isothebaine (i) methiodide and methyl ether methiodide [V. V. Kiselev and R. A. Konovalova, *J. Gen. Chem. USSR*, **19**, 148 (1949)].

Further Hofmann degradation of the methine base X methiodide proceeds readily with the formation of the same readily polymerized olefin XVIII (Et = CH=CH<sub>2</sub>) as is obtained by the degradation of the isomethine methyl ether (XI, R = Me) methiodide. Hydrogenation of the methine base X proceeds rapidly and gives the dihydromethine XIV, the methiodide of which can be degraded to a nitrogen-free product XVI isomeric with that XVIII obtained by the degradation of the dihydroisomethine methyl ether (XV, R = Me) methiodide. These two nitrogen-free products afford the same 2,2'-diethyl-5,6,5'-trimethoxydiphenyl (XVII) on catalytic reduction.

The spectra of the various compounds in this series are in accord with the assigned structures. The ultraviolet spectra of the bases X and XI, R = H, and the nitrogen-free products XVI and XVIII are styrenoid, and the infrared spectra of all four compounds show bands at 10.77–10.83  $\mu$  attributed to the vinyl group, whereas the spectra of the bases VII (R = H), XV (R = H), XV (R = Me), XIV, XII, and the nitrogen-free product XVII, from which the vinyl compounds are derived or into which they have been converted, show no absorption bands in this region.

The nmr spectrum of neodihydrothebaine (VII, R = H) shows a complex signal at  $\delta$  7.4–6.6 (5 aromatic H) and signals at  $\delta$  5.25 (OH), 3.86 (OCH<sub>3</sub>), 3.75 (OCH<sub>3</sub>), approximately 2.5, complex (8 H as CH<sub>2</sub>), and 2.25 (NCH<sub>3</sub>). The spectrum of the isomethine XI (R = H) shows a complex signal at  $\delta$  7.8–6.6 (5 aromatic H) and signals at  $\delta$  5.69 and 5.25 (double doublet, C-16 H,  $J_{16,16 \text{ trans}}$  = 18 cps;  $J_{16,16}$  = ca. 3 cps),  $\delta$  5.09 and 4.82 (double doublet, C-16 H,  $J_{16,16 \text{ cis}}$  = 10 cps;  $J_{16,16}$  = ca. 3 cps),  $\delta$  5.90 (OH), 3.85 (OCH<sub>3</sub>), 3.76 (OCH<sub>3</sub>), ca. 2.35 (4 H as CH<sub>2</sub>), and 2.0 (6 H as NMe<sub>2</sub>). In dimethyl sulfoxide the hydroxyl proton of the isomethine gave a signal at  $\delta$  7.95, and the signal due to the C-15 proton, which was obscured in the spectrum of the base in deuteriochloroform by the aromatic and hydroxyl proton signals, appeared as a double doublet with centers at  $\delta$  6.17 and 5.77 ( $J_{15,16 \text{ trans}}$  = 18 cps;  $J_{15,16 \text{ cis}}$  = 10 cps). The spectrum of 2,2'-diethyl-5,6,5'-trimethoxydiphenyl (XVII) showed signals at  $\delta$  7.6–6.6 (5 aromatic H), 3.9, 3.8, and 3.59 (3OCH<sub>3</sub>), 2.3 (quartet, 4 H), and 1.02 (triplet 6H), the latter two signals being attributable to two ethyl groups in virtually identical environments.

The iminium salt VIII is very rapidly decomposed by dilute acids and even by water, and the product may be assumed to be the amino aldehyde V, since on warming with mineral acid the iminium salt is converted into thebenine (II), which is the product of cyclodehydration of the aldehyde V.<sup>6</sup> From the mechanism of this cyclodehydration thebenine, not its O-methyl ether, would be expected to be the product of this reaction.

Attempts to isolate the amino aldehyde V were all unsuccessful and led to the recovery of a new base isomeric with thebaine in empirical formula and showing an infrared absorption band at 1645 cm<sup>-1</sup> indicating that the base is an enamine. This base, like the iminium salt VIII is very rapidly converted by hot 2 N

(6) In the earlier communication<sup>2</sup> thebenine was not clearly identified as the product of this reaction. The iminium salt used in that work was not freshly isolated, and the use of partially autoxidized material has a profound effect on the fluorescence of the resulting thebenine in alkaline solution, though not in acids.

hydrochloric acid into thebenine (II), presumably by way of its hydrolysis product, the amino aldehyde V. The simplest structure for this enamine would be that shown in formula I, which could be formed from the amino aldehyde V or directly by deprotonation of the iminium salt VIII, and the nmr spectrum of the base is compatible with such a structure. The spectrum shows signals at  $\delta$  6.9–6.6 (5 aromatic H), 6.2 (doublet, C-10 H,  $J_{10,9 \text{ cis}} = \text{ca. } 13 \text{ cps}$ ), 4.55 (doublet, C-9 H,  $J_{9,10 \text{ cis}} = \text{ca. } 13 \text{ cps}$ ), 4.65 (OH), 3.9 ( $\text{OCH}_3$ ), 3.81 ( $\text{OCH}_3$ ),  $\text{ca. } 2.6$  (4 H as  $\text{CH}_2$ ), and 2.35 ( $\text{NCH}_3$ ). This structure for the product is untenable, however, since on reduction catalytically or with sodium borohydride the enamine is reduced to an uncharacterizable base, which is clearly different in solubility,  $R_f$  value, and sign of optical rotation from neodihydrothebaine (VII,  $R = \text{H}$ ), although the two bases have virtually identical infrared absorption spectra. The only rational explanation of these results is that the enamine has the dimeric structure IV, the 18-membered ring of which might be expected to be formed from the amino aldehyde V more readily than the nine-membered ring of the simpler base I, since rings of the latter size are notoriously difficult to close. The nmr spectrum of the enamine is equally compatible with the structures IV and I in which the environments of the protons are virtually identical. Similarly, the environments of all of the atoms in neodihydrothebaine (VII,  $R = \text{H}$ ) and the base that would result from the reduction of the enamine IV are virtually identical, and it is reasonable to assume that the infrared absorption spectra of the two bases would be almost indistinguishable. The sign of optical rotation of the reduced enamine is the same as that of the isomethine XI ( $R = \text{H}$ ), in which the relatively rigid nine-membered ring of neodihydrothebaine (VII,  $R = \text{H}$ ) has been cleaved. Hydrolysis of the enamine IV would, of course, afford the amino aldehyde V, convertible by acids to thebenine (II). Formation of the enamine IV from the amino aldehyde V would be expected to be accompanied by the formation of a small amount of the enamine I and a considerable quantity of a linear polymeric enamine, and indeed a very good yield of crude enamine can be obtained but only about 25–30% of this is recoverable as a crystalline solid from 2-ethoxyethanol, and material recovered from the mother liquors defies all attempts at crystallization. Catalytic reduction of the crude enamine, however, affords about 5–8% of neodihydrothebaine, readily separable from other products by virtue of its solubility in ether. A good yield of thebenine is, however, obtained from the crude enamine on boiling with 2 *N* hydrochloric acid, as would be expected, since all three possible enamines would give the amino aldehyde V on hydrolysis. These results suggest that the crude enamine consists of about 5% of the simple base I, 30% of the dimeric base IV, and 65% of a mixture of polymeric enamines.

## Experimental Section

**Reaction of Thebaine with Anhydrous Magnesium Iodide.** A solution of anhydrous magnesium iodide (28 g, 0.1 mole) prepared from iodine (25.6 g) and excess (8 g) of magnesium in dry ether (200 ml) and dry benzene (300 ml) was added over 45 min to a vigorously stirred boiling solution of thebaine (31.1 g, 0.1 mole) in dry benzene (250 ml) under nitrogen. A light green-brown precipitate rapidly formed. The mixture was stirred under reflux for another 45 min. For most purposes this mixture was used

directly without isolation of the product. Isolation of the product by filtration of the mixture afforded a solid which, on washing well with ether and rapid drying in air, was obtained as an off-white powder that rapidly became green and degenerated to a sticky dark product in moist air.

**Oxidation of the Thebaine–Magnesium Iodide Reaction Product VIII.** The product of the above reaction, isolated as above (30 g) was vigorously stirred on the boiling water bath with water (350 ml), potassium hydroxide (50 g), and potassium permanganate (300 g) over a period of 4 hr, the oxidizing agent being added in portions of 50 g. The mixture was filtered, and the residue was washed with three 100-ml portions of boiling water. The filtrate was heavily contaminated with colloidal manganese dioxide which was coagulated by passing sulfur dioxide through the solution, which was filtered, concentrated to 300 ml, and acidified by the cautious addition of concentrated hydrochloric acid. Continuous ether extraction of the resulting mixture over 2 days afforded, on evaporation of the dried extract, a solid product that gave a derivative of fluorescein on fusion with resorcinol and concentrated sulfuric acid. A portion of this material was dissolved in aqueous methylamine, and the solution was evaporated. The residue was heated strongly and the volatile matter evolved was condensed and recrystallized from ethanol, when 4-methoxy-*N*-methylphthalimide was obtained as very pale yellow needles, mp  $156^\circ$  alone or mixed with an authentic specimen. A further portion of the oxidation product was heated alone and the volatile matter was condensed and recrystallized from a 1:1 mixture of benzene and light petroleum (bp  $60\text{--}80^\circ$ ); 4-methoxyphthalic anhydride was obtained as pale yellow needles, mp  $94^\circ$  alone or mixed with an authentic specimen.

**Action of Hydrochloric Acid on the Thebaine–Magnesium Iodide Reaction Product VIII.** The freshly isolated reaction product (4 g) was boiled with 2 *N* hydrochloric acid (20 ml) for 5 min. The mixture was cooled and basified with ammonia, and the amorphous product was collected and washed well with water. Comparative chromatographic studies on thin layer plates indicated that this product was thebenine (II). It was dissolved in hot 2 *N* hydrochloric acid (15 ml), and the solution was cooled in ice when a viscous hydrochloride separated. This crystallized on trituration with ice-water and was obtained as pale yellow needles, mp  $234\text{--}236^\circ$ , identical in melting point, mixture melting point, infrared absorption, and  $R_f$  value with thebenine hydrochloride.

**Neodihydrothebaine (VII,  $R = \text{H}$ ).** a. A solution of lithium aluminum hydride (4.5 g) in anhydrous ether (200 ml) was added to a vigorously stirred suspension of the product of reaction of thebaine (31.1 g) with anhydrous magnesium iodide (28 g) in ether-benzene. A vigorous reaction ensued and the light green-brown suspended material became white. The mixture was stirred for 1 hr; the excess of hydride was cautiously decomposed by the addition of water, and the product was dissolved by the addition of 2 *N* hydrochloric acid. The organic layer was discarded, and the aqueous layer, after extraction once with ether to remove all of the benzene, was diluted with saturated sodium potassium tartrate and ammonium chloride, covered with a layer of ether, and basified with ammonia. The precipitated base dissolved rapidly in the ether, which was separated, dried, and passed through a column of Florisil (60–100 mesh) (30 g) to remove a small amount of purple material. Evaporation of the ether then afforded neodihydrothebaine (VII,  $R = \text{H}$ ) as a very pale brown oil that slowly crystallized on standing. The base was recrystallized with difficulty from 90% methanol below  $0^\circ$ , when it was obtained as almost colorless prisms, mp  $98\text{--}100^\circ$ ,  $[\alpha]_D^{20} +63.7^\circ$  ( $c$  2.0,  $\text{CHCl}_3$ ).

*Anal.* Calcd for  $\text{C}_{19}\text{H}_{23}\text{NO}_2$ : C, 73.3; H, 7.4. Found: C, 73.6; H, 7.5.

The base was readily soluble in aqueous alkalis, and the solution coupled instantaneously with diazotized sulfanilic acid to give a blood red dye.

The methiodide formed rapidly in ethanol and was obtained as pale cream prisms, mp  $249\text{--}250^\circ$  from ethanol.

*Anal.* Calcd for  $\text{C}_{19}\text{H}_{23}\text{NO}_2 \cdot \text{CH}_3\text{I}$ : C, 53.1; H, 5.6. Found: C, 52.8; H, 5.8.

The methyl ether methiodide was prepared by the addition of methyl sulfate to a solution of the phenol in aqueous potassium hydroxide, when the initial precipitate of the methyl ether rapidly dissolved, followed by the addition of potassium iodide. The precipitated salt crystallized rapidly and was collected and recrystallized from water as white plates, mp  $260\text{--}261^\circ$ .

*Anal.* Calcd for  $\text{C}_{20}\text{H}_{25}\text{NO}_2 \cdot \text{CH}_3\text{I} \cdot 0.5\text{H}_2\text{O}$ : C, 52.7; H, 6.1. Found: C, 52.8; H, 6.0.

b. The same base was obtained by reduction of the suspension of the iminium salt VIII in ether-benzene by the addition of

sodium borohydride (8.0 g) in hot ethanol (200 ml). The finely divided suspension rapidly coagulated to a sticky green mass that dissolved quickly as the reduction proceeded. The mixture was finally diluted with aqueous ammonium chloride, and the ether-benzene layer was removed, washed twice with water, dried, passed through Florisil as in part a above, and evaporated *in vacuo*. The residual base was identified with that produced in part by a thin layer chromatography and by conversion into the methiodide and methyl ether methiodide.

Identical results were obtained when the iminium salt VIII was isolated, washed with dry ether, and added to a vigorously stirred solution of sodium borohydride in ethanol, with isolation of the product by the addition of aqueous ammonium chloride and ether extraction.

**Neodihydrothebaine Isomethine (XI, R = H).** Potassium hydroxide was added to a boiling solution of neodihydrothebaine methiodide (4 g) in water (50 ml) until the solution became turbid due to the separation of a potassium salt. The solution was clarified by the addition of a small volume of water and then boiled for 30 min, during which time a viscous oil separated. The mixture was cooled in ice-salt and the liquid decanted from the hard brown glass, which was then dissolved in 2 *N* hydrochloric acid (50 ml) and methanol (30 ml). The base was precipitated as a crystalline solid by the slow addition of aqueous ammonia to the vigorously stirred acid solution, and was collected, washed with water, and recrystallized from aqueous methanol, and obtained as off-white prisms, mp 128–129°,  $[\alpha]_D^{25} -24.5^\circ$  (*c* 2.0, CHCl<sub>3</sub>).

*Anal.* Calcd for C<sub>16</sub>H<sub>21</sub>NO<sub>2</sub>: C, 73.5; H, 7.7. Found: C, 73.7; H, 7.1.

The methiodide was obtained from ethanol as off-white prisms, mp 268–269°.

*Anal.* Calcd for C<sub>16</sub>H<sub>21</sub>NO<sub>2</sub>·CH<sub>3</sub>I: C, 53.8; H, 6.0. Found: C, 53.8; H, 5.9.

The methyl ether methiodide was obtained by the addition of aqueous potassium iodide to the aqueous solution finally resulting from the methylation of the base in aqueous potassium hydroxide with methyl sulfate. It was readily recrystallized from water and obtained as white needles, mp 205°.

*Anal.* Calcd for C<sub>17</sub>H<sub>23</sub>NO<sub>2</sub>·CH<sub>3</sub>I: C, 54.6; H, 6.2. Found: C, 54.4; H, 6.0.

The methyl ether methoperchlorate was prepared by the addition of perchloric acid to a solution of the methyl ether methiodide in aqueous ethanol. On recrystallization from aqueous ethanol it was obtained as white elongated plates, mp 161–162°.

*Anal.* Calcd for C<sub>17</sub>H<sub>23</sub>NO<sub>2</sub>·CH<sub>3</sub>ClO<sub>4</sub>: C, 58.1; H, 6.65. Found: C, 57.9; H, 6.6.

**Cyclization of Neodihydrothebaine Isomethine (XI, R = H).** Neodihydrothebaine isomethine (0.5 g) was boiled with concentrated hydrochloric acid (5 ml) for 3 min. The solution was diluted with water and poured into an excess of aqueous potassium hydroxide. The precipitated nonphenolic base XII was isolated by ether extraction, but could not be induced to crystallize, and was characterized as the picrate, yellow prisms, mp 208–210°.

*Anal.* Calcd for C<sub>16</sub>H<sub>21</sub>NO<sub>2</sub>·C<sub>6</sub>H<sub>3</sub>N<sub>3</sub>O<sub>7</sub>: C, 56.2; H, 5.1. Found: C, 56.4; H, 5.4.

**Neodihydrothebaine Dihydroisomethine (XV, R = H).** Neodihydrothebaine isomethine (XI, R = H) (1 g) was shaken under hydrogen at 20° (750 mm) in the presence of 10% palladium-on-charcoal catalyst (0.25 g). Hydrogen (70 ml) was absorbed over 15 min. Filtration and evaporation of the solution afforded the dihydroisomethine (XV, R = H) as a colorless oil,  $[\alpha]_D^{25} -10.0^\circ$  (*c* 2.1, CHCl<sub>3</sub>), that could not be crystallized.

The methiodide was obtained readily as white prisms, mp 286–288° from ethanol.

*Anal.* Calcd for C<sub>16</sub>H<sub>21</sub>NO<sub>2</sub>·CH<sub>3</sub>I: C, 53.55; H, 6.4. Found: C, 53.6; H, 6.7.

The methyl ether methiodide was obtained as white prisms, mp 228–230° from water.

*Anal.* Calcd for C<sub>17</sub>H<sub>23</sub>NO<sub>2</sub>·CH<sub>3</sub>I: C, 54.5; H, 6.6. Found: C, 54.6; H, 6.6.

**Hofmann Degradation of Neodihydrothebaine Isomethine Methyl Ether (XI, R = Me) Methiodide.** Potassium hydroxide was added to a boiling solution of neodihydrothebaine isomethine methyl ether methiodide (1 g) in water (25 ml) until separation of an oil began. The mixture was then boiled for 1 hr, during which time a base (trimethylamine) was evolved, and an insoluble oil separated. The mixture was cooled and extracted with ether, and the ether extract was shaken twice with 2 *N* hydrochloric acid and evaporated, to leave an uncrystallizable fluorescent (blue) neutral oil that was rapidly converted into a rubbery solid on attempted distillation or

(more slowly) on standing. Thin layer chromatographic studies indicated that this product, presumably the divinylidiphenyl XVIII (Et = CH=CH<sub>2</sub>), was identical with the product of degradation of neodihydrothebaine methine methyl ether (X) methiodide.

**Hofmann Degradation of Neodihydrothebaine Dihydroisomethine Methyl Ether (XV, R = Me) Methiodide.** Neodihydrothebaine dihydroisomethine methyl ether methiodide (2 g) was degraded by the process given above to yield 2'-ethyl-5,6,5'-trimethoxy-2-vinylidiphenyl (XVIII) as a pale brown oil which was distilled under high vacuum, and was obtained as a colorless oil, bp 190–200° (bath temp) (0.05 mm).

*Anal.* Calcd for C<sub>19</sub>H<sub>24</sub>O<sub>3</sub>: C, 76.5; H, 7.6. Found: C, 76.4; H, 7.7.

**2,2'-Diethyl-5,6,5'-trimethoxydiphenyl (XVII).** 2'-Ethyl-5,6,5'-trimethoxy-2-vinylidiphenyl (XVIII) (0.8 g) in ethanol (25 ml) was shaken under hydrogen at 20° (760 mm) in the presence of 10% palladium-on-charcoal catalyst (0.25 g). Hydrogen (66 ml) was absorbed over 10 min. The solution was filtered and evaporated, and the residual oil was distilled when the diphenyl XVII was obtained as a colorless oil, bp 190–200° (bath temperature) (0.05 mm).

*Anal.* Calcd for C<sub>19</sub>H<sub>24</sub>O<sub>3</sub>: C, 76.1; H, 8.1. Found: C, 76.2; H, 8.1.

The same product, identical in behavior with the above on thin layer chromatography, was obtained by the hydrogenation of 2-ethyl-5,6,5'-trimethoxy-2'-vinylidiphenyl (XVI), obtained by the degradation of the methiodide of neodihydrothebaine dihydro-methine methyl ether (XVI).

**Neodihydrothebaine Methine Methyl Ether (X).** Neodihydrothebaine methyl ether methiodide (5 g) was dissolved in boiling water (50 ml), and potassium hydroxide was added to the solution until separation of an oil began. The mixture was then boiled for 30 min, cooled, and diluted, and the product was isolated by ether extraction. Thin layer chromatographic studies showed that the uncrystallizable oil contained two bases. It was converted into the methiodide by heating with methyl iodide and ethanol, and on cooling the solution slowly deposited neodihydrothebaine isomethine methyl ether methiodide (0.5 g), mp 205°, identical with the salt prepared from the isomethine (see above). Evaporation of the mother liquors after removal of this salt afforded material that could not be obtained crystalline from ethanol or from water. It was converted into neodihydrothebaine methine methyl ether methoperchlorate by the addition of perchloric acid to a solution of the methiodide in water. The methoperchlorate was obtained as white needles, mp 150–151°, on recrystallization from water.

*Anal.* Calcd for C<sub>17</sub>H<sub>23</sub>NO<sub>2</sub>·CH<sub>3</sub>·CH<sub>3</sub>ClO<sub>4</sub>: C, 58.1; H, 6.65. Found: C, 58.1; H, 6.55.

**Oxidation of Neodihydrothebaine Methine Methyl Ether.** Neodihydrothebaine methine methyl ether, containing some of the isomethine methyl ether (1.8 g), was stirred on the boiling water with potassium hydroxide (2.0 g), potassium permanganate (4.0 g), and water (50 ml) for 4 hr. The mixture was filtered, and the yellow filtrate was acidified with hydrochloric acid; the precipitated product was isolated by ether extraction and obtained as a viscous yellow oil. Thin layer chromatographic studies showed this material to consist of two yellow products and about 10% 5,6,5'-trimethoxydiphenic acid. The material was dissolved in 2 *N* potassium hydroxide solution (50 ml), and the solution was warmed on the water bath for 10 min with 30% hydrogen peroxide (1 ml). Acidification of the solution then afforded 5,6,5'-trimethoxydiphenic acid (1.2 g) as white prisms, mp 215°, from aqueous methanol; the melting point was undepressed on mixing with authentic specimens prepared from acetylthebaol and phenyldihydrothebaine.

The trimethoxydiphenic acid was warmed with concentrated sulfuric acid at 50° for 15 min. Dilution of the solution with water precipitated 1,5,6-trimethoxyfluorenone-4-carboxylic acid as yellow needles from 50% acetic acid, mp 256° alone or mixed with an authentic specimen.

**Hofmann Degradation of Neodihydrothebaine Methine Methyl Ether (X) Methiodide.** Degradation of the methiodide of the base X by the process described above for the degradation of neodihydrothebaine isomethine methyl ether methiodide afforded a neutral product identical with that obtained in that degradation.

**Neodihydrothebaine Dihydromethine Methyl Ether (XIV).** Neodihydrothebaine methine methyl ether (containing about 10% of the isomethine methyl ether) (5.4 g) was shaken in ethanol (50 ml) with 10% palladium on charcoal (0.25 g) under hydrogen at 20° (760 mm). Hydrogen (348 ml) was absorbed over 40 min. Filtration and evaporation afforded a noncrystalline gum, which was converted into the methiodide. Two recrystallizations of the methiodide afforded the dihydromethine methyl ether methiodide

the isomethine derivative (tlc) as white prisms, mp 200–

Calcd for  $C_{21}H_{23}NO_3 \cdot CH_3I$ : C, 54.5; H, 6.6. Found: H, 6.6.

**Degradation of Neodihydrothebaine Dihydromethine Ether (XIV) Methiodide.** The methiodide (2.0 g) was dissolved in boiling aqueous potassium hydroxide, when trimethylamine evolved and 2-ethyl-5,6,5'-trimethoxy-2'-vinylidiphenyl ether was isolated by ether extraction and distillation and obtained less oil, bp 190–200° (bath temperature) (0.05 mm).

Calcd for  $C_{19}H_{23}O_3$ : C, 76.5; H, 7.6. Found: C, 7.4.

Catalytic reduction of this compound proceeded readily in the presence of 10% palladium on charcoal, and gave 2,2'-diethylnethoxydiphenyl (XVII), identical in thin layer chromatographic behavior with material prepared by the reduction of 2'-5'-trimethoxy-2-vinylidiphenyl (XVIII) described above.

**Kryptothebaine (IV).** The product of reaction of thebaine (31.1 g) with anhydrous magnesium iodide in ether–benzene suspension and with 2 *N* hydrochloric acid. A sticky insoluble mass (bly a hydriodide) was obtained, and the aqueous and solutions were poured off. After the material was washed in methanol, the solution was diluted with ice water and basified with ammonia. A further quantity of base was obtained by adding ammonia to the aqueous acid layer separated above. The precipitated solid was collected and redissolved from ethanol and from aqueous 2-ethoxyethanol; product, kryptothebaine (IV), was obtained in each case as gray prisms, mp 274° (8.5 g). Recrystallization from 2-ethoxyethanol with the addition of a drop of aqueous

sodium dithionite gave the enamine as pale cream prisms, mp 274°, but these rapidly became green on standing, the color darkening to almost black after several days.

**Anal.** Calcd for  $C_{20}H_{23}N_2O_4$ : C, 73.3; H, 6.75; mol wt, 622. Found: C, 73.3; H, 6.8; mol wt (Rast in camphor), 586.

Reduction of this base catalytically over 10% palladium on charcoal was sluggish and was only complete after 10 hr, and reduction with sodium borohydride was slow even in boiling 2-ethoxyethanol. The same base was obtained in each case, and unlike neodihydrothebaine (which it closely resembled in infrared absorption), it was completely insoluble in ether. No crystalline salts of this uncrystallizable base could be prepared.

Catalytic reduction of the crude product (2 g) obtained on basification of the aqueous methanolic solution of the hydriodide, however, gave, slowly, a product part of which dissolved in ether. Evaporation of the ether gave neodihydrothebaine (0.16 g) identified as its methiodide, mp 249–250° from ethanol.

**Reaction of Kryptothebaine (IV) with Hydrochloric Acid.** Kryptothebaine (IV), prepared as above (2 g), was boiled with 2 *N* hydrochloric acid (10 ml) for 5 min. The solution, on cooling, deposited a viscous gum (2.0 g), which crystallized from water at 0° as yellow needles, mp 234–236°, identical in melting point, mixture melting point, infrared absorption, and  $R_f$  value with thebenine (II) hydrochloride prepared in the same way from thebaine.

## The Structures of Deserpideine and Raujemidine<sup>1</sup>

E. Smith,<sup>2</sup> R. S. Jaret, R. J. Shine, and M. Shamma<sup>3</sup>

Contribution from S. B. Penick and Company, New York, New York, and the Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania. Received December 10, 1966

**Abstract:** The indole alkaloids deserpideine and raujemidine correspond to expressions I and Ia, respectively. The most interesting transformation of deserpideine is its hydrogenation and hydrogenolysis with Adams catalyst to yield products II, III, X, and XII.

Initial investigation of the alkaloids of *Rauwolfia la Jacq.* by Salkin and his group<sup>4</sup> led to the isolation of deserpideine, isoreserpiline, isoreserpinine, raunititidine, reserpiline, and reserpinine.

We have now found that the weakly basic alkaloid deserpideine from certain samples of *R. nitida* yields, in addition to the known alkaloid deserpideine (II), a crystalline alkaloid, deserpideine (I),  $C_{22}H_{26}N_2O_8$ , mp 152°,  $[\alpha]^{25}_D - 133^\circ$  (pyridine), whose ultraviolet spectrum is identical with its companion deserpideine. The infrared spectrum of deserpideine is very similar to that of deserpideine, but varies

Supplementary communications of some of these results appeared in (a) E. Smith, R. S. Jaret, M. Shamma, and R. J. Shine, *J. Am. Chem. Soc.* 88, 1083 (1966); (b) M. Shamma and R. J. slightly from the latter in the fingerprint region. In analogy with deserpideine (II), the Bohlmann bands between 3.4 and 3.6  $\mu$  were missing in deserpideine (I), indicating a *cis* C–D ring fusion.

The chemistry of deserpideine (I) initially indicated a behavior that somewhat paralleled the chemistry of deserpideine (II). The reaction of deserpideine (I) with sodium methoxide at room temperature gave the expected methyl 3,4,5-trimethoxybenzoate (IIIa) and methyl deserpideate (IV),  $C_{22}H_{26}N_2O_4 \cdot H_2O$ , mp 159–162°,  $[\alpha]^{25}_D + 8^\circ$  (pyridine). Hydrolysis of either deserpideine or methyl deserpideate with potassium hydroxide in aqueous methanol gave deserpideic acid (V),  $C_{21}H_{24}N_2O_4$ , mp 224–226°,  $[\alpha]^{25}_D - 29^\circ$  (50% methanol–water), which could be converted to deserpideic acid lactone (VI),  $C_{21}H_{22}N_2O_3$ , mp 159–161°,  $[\alpha]^{25}_D - 58^\circ$  (50% methanol–water), on treatment with acetic anhydride in pyridine. When deserpideic acid lactone was allowed to stand at 0° in sodium methoxide in methanol, methyl deserpideate (IV) was obtained. Deserpideine (I) itself could be reconstituted by treatment of methyl deserpideate with 3,4,5-trimethoxy-

benzoyl chloride. The reaction cycle was completed by converting deserpideic acid (V) to methyl deserpideate (IV). This esterification could be accomplished by either of two methods. The reaction of deserpideic acid with diazomethane proceeded poorly giving only a 25% yield of methyl deserpideate, the remainder of the product being unreacted starting material. The Fischer esterification, however, went smoothly at room temperature giving an 88% yield of methyl deserpideate.

Oxidation of deserpideine with 2 molar equiv of lead tetraacetate and reduction of the crude reaction product with borohydride gave a new compound, 3-isodeserpideine (VII), crystallized as the nitrate and the methiodide salts.

On the other hand, if the methanolysis of deserpideine with sodium methoxide were allowed to proceed in refluxing methanol, a considerable amount of a new compound was obtained. This material, mp 174–176°, analyzes for  $C_{21}H_{20}N_2O_2 \cdot 0.5C_2H_5OH$ , has a very high dextrorotation,  $[\alpha]^{25}_D +288^\circ$  (pyridine), and an infrared spectrum exhibiting only one carbonyl band which appears at  $5.83 \mu$ . The nmr spectrum shows one methoxyl singlet at  $\delta$  3.88 due to three protons, and the mass spectrum has a molecular ion peak at  $m/e$  332. From these data, structure VIII was considered for this new compound.

To ascertain this structural assignment, our highly dextrorotatory compound, presumed to be VIII, was converted to the alcohol IX by means of lithium aluminum hydride and compared with authentic IX that we had synthesized by a route developed by Elderfield and Fischer.<sup>5</sup> Comparison of the two alcohols (IX) as their hydrobromide salts showed the two salts to be identical. They both had identical infrared spectra taken as KBr pellets and they showed the same characteristics on melting. Paper chromatography  $R_f$  values in a number of solvent systems further showed the identity of the two materials. The structure of the highly dextrorotatory compound was thus shown to be 11-demethoxytetrahydroalstoniline (VIII), and its formation has no analogy in the reserpine series.

Significant information about the stereochemistry of the new alkaloid could be derived from a study of its rate of quaternization with methyl iodide. Rates of methiodide formation had previously proven to be a useful tool in the study of the stereochemistry of the yohimbinoind alkaloids.<sup>6</sup> These rates were determined in acetonitrile solution using pseudo-first-order kinetics, a large excess of methyl iodide being present. The pseudo-first-order rate constants for deserpideine and its derivatives and a variety of other indole alkaloids are given in Table I. In the yohimbine series, such a very fast rate as that exhibited by deserpideine (I) and its derivatives IV and VI is associated with the pseudo-configuration, but in the present case a more specific statement is desired; namely, that in deserpideine and its derivatives the basic nitrogen is unhindered.

A second piece of data of great utility was supplied by mass spectrometry. Since deserpideine free base is rather unstable, the mass spectra were run on its more stable crystalline derivatives, methyl deserpideate (IV) and deserpideic acid lactone (VI). The molecular ion peaks of methyl deserpideate and the lactone, at  $m/e$

Table I. Pseudo-First-Order Rates of Methiodide Form.

Alkaloids and derivatives	$k \times 10^4$ , sec <sup>-1</sup>	S ch
Deserpideine (I)	300	
Methyl deserpideate (IV)	350	
Deserpideic acid lactone (VI)	220	
3-Isodeserpideine (VII)	31	
Deserpidine (II)	7.2	E
16-Methyl-19-methoxyalloyohimbane (XI)	2.5	A
$\alpha$ -Yohimbine methyl ether (XII)	1.1	A
3-Isodeserpidine	1.0	A
Yohimbine	48.7	N

382 ( $C_{22}H_{26}N_2O_4$ ) and  $m/e$  350 ( $C_{21}H_{22}N_2O_3$ ), respectively were two mass units less than for the corresponding compounds in the deserpideine series. These results immediately indicated the presence of either an unsaturation or an additional ring in compounds of the deserpideine series, and further confirmed the assignment  $C_{22}H_{26}N_2O_4$  formulation to deserpideine, which has two mass units less than that for deserpideine. The results between an unsaturation and an extra ring was decided by the study of a third piece of data, the nmr spectra. The spectra of deserpideine and its derivatives show absorption at  $\delta$  5.55 corresponding to one proton. This absorption is in the region of vinylic absorption, deserpideine possesses a trisubstituted double bond which is not conjugated to the chromophoric system. The most likely positions for such a double bond were C-14(15) or C-19(20).

In an attempt to reduce this isolated double bond deserpideine was hydrogenated using Adams catalyst in ethanol at room temperature. The alkaloid did not take up hydrogen, but only slowly. If the reaction were allowed to proceed for 12 hr, a complex mixture of products ensued.

A thin layer chromatogram of the reduction product showed at least ten spots. The crude hydrogenation mixture was, therefore, separated into an acidic, a basic, and a neutral fraction by classical extraction techniques. A crystalline compound was obtained in 68% yield from the acidic fraction which was characterized as 3,4,5-trimethoxybenzoic acid (III). Identification of this material strongly indicated the position of the double bond to be at C-19(20), and hydrogenolysis of the allylic 3,4,5-trimethoxybenzyl group can then occur.

Following removal of the acidic and neutral components, crystallization of the basic fraction was possible, and a white crystalline compound was obtained. This compound was shown to be identical with authentic deserpidine (II) in a number of ways. The compounds had the same infrared spectra in chloroform and in acetonitrile solution, and their nmr spectra were also identical. Thin layer chromatograms in a number of solvent systems always resulted in the two compounds having the same  $R_f$  values. A methiodide rate study showed the synthetic material to have a rate of  $10^{-4}$  sec<sup>-1</sup>, characteristic of the expected epiallonyl configuration. Finally, the melting points (224–226°) were the same and a mixture melting point was pressed. As a precautionary measure, rotation was determined and found to be the same,  $[\alpha]^{25}_D +288^\circ$  in chloroform. This shows that the deserpidine isolated from the hydrogenation reaction has the same

(5) R. Elderfield and B. Fischer, *J. Org. Chem.*, **23**, 949 (1958).

(6) M. Shamma and J. Moss, *J. Am. Chem. Soc.*, **83**, 5038 (1961); M. Shamma and J. Richey, *ibid.*, **85**, 2507 (1963).

solute configuration as natural deserpidine. Thus, the identity of the two compounds was clearly established, and this transformation proves the stereochemistry of deserpidine to be as indicated in I.

The neutral fraction readily crystallized into a colorless compound which contained no carbonyl band between 5 and 6  $\mu$ , but possessed a very intense absorption at 6.13  $\mu$ . The loss of basicity of the nitrogen and the disappearance of the ester carbonyl bands accompanied by the presence of the 6.13- $\mu$  peak clearly point to allylic hydrogenolysis of the C-21(N-4) bond followed by intramolecular ester-amide conversion to

form lactam X.<sup>7</sup> Further evidence for the structural assignment for the neutral compound is seen in the nmr and mass spectra of the material. The mass spectrum shows a molecular ion peak at  $m/e$  338 which is the correct molecular weight calculated for 16-methyl-19-methoxy-21-oxoyohimbane (X). The nmr spectrum shows only one methoxyl absorption at  $\delta$  3.25 and shows a C-CH<sub>3</sub> doublet at  $\delta$  1.03. The absence of a vinylic absorption and the presence of the C-CH<sub>3</sub> doublet clearly indicate reduction of the double bond

(7) F. L. Weisenborn and H. E. Applegate, *J. Am. Chem. Soc.*, **78**, 2021 (1956).

originally present in I. The stereochemistry of the asymmetric centers at C-3, C-15, C-19, and C-20 in lactam X must be as indicated from our knowledge of the stereochemistry of deserpideine. Upon reduction of lactam X with lithium aluminum hydride, 16-methyl-19-methoxyalloyohimbane (XI) was obtained which showed a molecular ion peak at  $m/e$  324 in accordance with the formula  $C_{21}H_{28}N_2O$ . The infrared spectrum showed no carbonyl absorption and specifically the band at  $6.13 \mu$  had disappeared. The rate of methiodide formation for compound XI was found to be  $2.5 \times 10^{-4} \text{ sec}^{-1}$  which is a slow rate strongly characteristic of an allo configuration.

After removing the crystalline deserpideine, the basic fraction of the hydrogenation product still contained several minor components as monitored by thin layer chromatography, and it was found possible to separate one additional basic component. The infrared spectrum of this compound showed the absence of the band at  $6.3 \mu$ , characteristic of the 3,4,5-trimethoxybenzoyl group, and the presence of Bohlmann bands at  $3.4\text{--}3.6 \mu$ . It was, therefore, assumed that this compound had lost the 3,4,5-trimethoxybenzoyl group *via* hydrogenolysis, and that the proton at C-3 had epimerized to the  $\alpha$  configuration. A rate of methiodide formation was needed to decide from which side of the molecule hydrogenation had occurred, and a choice had to be made between the normal and the allo configuration for the new base. The rate was found to be extremely slow,  $1.1 \times 10^{-4} \text{ sec}^{-1}$ , indicating an allo configuration and  $\alpha$  hydrogenation, so that the compound had to be the known  $\alpha$ -yohimbine methyl ether (XII).<sup>8</sup> Indeed, when the two compounds were compared, they were found to be identical. The isolation of this product further supports the assignment of stereochemistry of the asymmetric centers at C-15, C-16, and C-17 in deserpideine (I). The isomerization of C-3 in this reaction is not surprising since it is known that reserpine is converted to 3-isoreserpine under these reducing conditions.<sup>9</sup>

Catalytic hydrogenation of 3-isodeserpideine (VII) under the same conditions as for deserpideine also led to a complex mixture of products. Extraction of the acidic material gave a 65% yield of 3,4,5-trimethoxybenzoic acid, the same yield as obtained from the hydrogenation of deserpideine. Addition of methanol to the amorphous material obtained after extraction of the acidic material caused it to crystallize. The crystalline material, obtained in a 28% yield, was shown to be a  $\alpha$ -yohimbine methyl ether (XII) by comparison with an authentic sample. The yield of this compound is significantly greater than in the hydrogenation of deserpideine which gave a 12% yield, and this would be expected since the hydrogen at C-3 is already in the  $\alpha$  configuration in 3-isodeserpideine (VII). A small amount of 3-isodeserpideine (XIII) also could be obtained from the hydrogenation.

Hydrogenation of methyl deserpideate (IV) with Adams catalyst led to a complex mixture of products. This reaction mixture was separated into a neutral lactam fraction and a basic fraction. Preparative thin layer chromatography of the basic fraction yielded

pure methyl deserpideate (XIV) which was shown identical with authentic material.

These data give compelling evidence that deserpideine must have structure I and is, therefore, 19-dehydrodeserpideine. The position of the double bond is demonstrated by the results of the hydrogenation experiments, the rate studies, and the formation of 1-methoxytetrahydroalstoniline (VIII). All asymmetric centers were shown to have the same stereochemistry as deserpideine.

Application of Hudson's lactone rule<sup>10</sup> to the deserpideine series to determine the absolute configuration led to ambiguous results. When the rotations were measured in methanol, the change in the molecular rotation from deserpideic acid,  $[M]^{25D} -107^\circ$ , to deserpideic acid lactone,  $[M]^{25D} -206^\circ$ , was found to be  $-99^\circ$ , indicating that the hydroxyl group at C-18 has the  $\alpha$  configuration. This configuration is opposite to that assigned on the basis of the isolation of (–)-deserpideine from the hydrogenation reaction. However, when the rotations were measured in pyridine, the change in molecular rotation was found to be  $+73.3^\circ$ , indicating a  $\beta$  configuration for the C-18 hydroxyl. Thus, the absolute configuration that may be assigned by use of Hudson's lactone rule is shown to be solvent dependent in the present case. This finding along with other known exceptions<sup>11–14</sup> shows that assignments of absolute configuration on the basis of Hudson's lactone rule should be done with extreme caution.

11-Demethoxytetrahydroalstoniline (VIII) has one asymmetric center and the compound is dextrorotatory, so that the contribution of C-3 to the asymmetry of the molecule must be dextrorotatory. The method of rotational differences had previously been applied to the C-3 hydrogen in the reserpine series.<sup>15</sup> It was found that when the hydrogen at C-3 was  $\alpha$ , this center made a large negative contribution to the molecular rotation. In the case of 11-demethoxytetrahydroalstoniline, the asymmetric center at C-3 makes a large positive contribution to the molecular rotation, and therefore the C-3 proton should have the  $\beta$  configuration. This is in agreement with the absolute configuration presently assigned to deserpideine on the basis of the isolation of (–)-deserpideine from the hydrogenation reaction.

It is fitting at this point to turn our attention to the alkaloid raujemidine obtained from *R. canescens* in 1956. This base had been reported to give an elemental analysis nearly identical with that of reserpine, and treatment with sodium methoxide yielded methyl 3,4,5-trimethoxybenzoate.<sup>16</sup> A rate of methiodide formation was, therefore, determined for raujemidine and found to be  $3.0 \times 10^{-2} \text{ sec}^{-1}$ . This very fast rate indicated that the molecule possesses an unhindered nitrogen. The nmr spectrum of raujemidine was similar to that of reserpine, but it possessed an additional vinyl absorption at  $\delta$  5.50. The relationship between raujemidine and deserpideine seemed obvious; it appeared

raujemidine was 19-dehydroreserpine (Ia), so that nidine stands to reserpine in the same relationship as deserpideine is related to deserpidine. To test this hypothesis, raujemidine was hydrogenated under the same conditions as deserpideine. It was found that the two compounds behaved similarly in the presence of platinum and hydrogen. Raujemidine hydrogenated slowly and gave a complex mixture of products. 3,4,5-trimethoxybenzoic acid (III) was extracted from the product and was shown to be identical with authentic material. This settled the position of the double bond at C-19. An infrared spectrum of the hydrolyzed residue showed an increased absorption at 6.13  $\mu$  due to the formation of a lactam. The residue was purified by preparative scale thin layer chromatography to give a band that possessed the same  $R_f$  value as reserpine (IIa) was examined in detail. This compound was purified from the silica gel and crystallized from ethanol. The crystalline compound was shown to be identical with authentic reserpine by comparing physical properties. They both had identical infrared spectra in chloroform and acetonitrile. The nmr spectra were practically superimposable, the melting points were identical, and a mixture melting point was undepressed. The  $R_f$  values in a number of solvent systems were identical. The structure of raujemidine was therefore settled as Ia, with a molecular formula  $C_{33}H_{38}N_2O_9$ . Raujemidine is the second member of the 19-dehydroyohimbinol series to be characterized. Further investigation with raujemidine was precluded by its instability, also by lack of sample. Very recently, Arndt and Djerassi isolated 19-dehydroyohimbine from *Aspidosiphon pyriforme* which represents the third member of the rare 19-dehydroyohimbine alkaloids.<sup>17</sup>

## Experimental Section

**Standard Experimental Procedures.** All microanalyses were performed by Midwest Microlab, Inc., Indianapolis, Ind., and by Zkoef Microanalytical Laboratory, Woodside, N. J. The melting points were taken either on a Nalge melting point apparatus or in a sealed capillary and are uncorrected. The nmr spectra were measured on a Varian Associates A-60 spectrometer with microcells purchased from Varian Associates, with deuteriochloroform as the solvent and tetramethylsilane as the internal standard. The mass spectra of a few derivatives were graciously obtained in the laboratories of Professor Carl Djerassi or Professor Klaus Biemann. The remainder of the mass spectra were obtained on a Nuclide 12-90-G1.1 mass spectrometer. Adsorbents were purchased from Applied Science Laboratories of State College, Pa., and were used to prepare the thin layer chromatography plates for this study. The spots were visualized by placing the plates in a fuming sulfuric acid vapor or by shining an ultraviolet light.

**Deserpideine (I).** The milled root of *R. nitida*, originally collected from the island of Hispaniola, was moistened with saturated potassium carbonate solution and extracted with benzene. The benzene extract was shaken with 0.5 M phosphoric acid. The acid solution was extracted at pH 2 with chloroform, and the chloroform layer was washed with potassium carbonate solution. Evaporation of the solvent left the weakly basic alkaloid fraction behind. The alkaloids were precipitated from ethanol solution as their picrate salts. The crude picrate salts were placed in chloroform solution and washed with aqueous sodium carbonate solution. The chloroform layer was then separated and the solvent evaporated. The residue was taken up in methanol, and the reserpine which was precipitated out was removed by filtration. After concentration to a small volume, the mother liquors were taken up in ethyl acetate to give a mixture of deserpideine and deserpideine. Crystallization of the hydrochloride salts from acetone gave deserpideine hydro-

chloride, which after recrystallization from methanol melted at 277° dec,  $[\alpha]^{25}_D -98.5^\circ$  (c 0.5, chloroform).

*Anal.* Calcd for  $C_{22}H_{27}ClN_2O_8$ : C, 62.68; H, 6.09; Cl, 5.78; N, 4.57; O, 20.87. Found: C, 62.49; H, 6.23; Cl, 5.76; N, 4.56; O, 20.81.

The free base was liberated from a chloroform solution of the hydrochloride with sodium carbonate and crystallized from ether, mp 149–152° dec,  $[\alpha]^{25}_D -133^\circ$  (c 1, pyridine),  $[\alpha]^{25}_D -108^\circ$  (chloroform).

*Anal.* Calcd for  $C_{22}H_{27}N_2O_8$ : C, 66.64; H, 6.29; N, 4.86; O, 22.20;  $SOCH_3$ , 26.87. Found: C, 66.62; H, 6.60; N, 4.91; O, 22.30;  $OCH_3$ , 26.30.

**Deserpideine Methiodide.** A solution of 100 mg (0.174 mmole) of deserpideine in 1.5 ml of ethyl acetate was prepared and cooled to 0°. To this slightly yellow solution, 1.0 ml of pure methyl iodide was added. The flask was flushed with nitrogen, stoppered, and allowed to stand at 0° for 4 hr. Evaporation of the excess methyl iodide caused an insoluble residue to form. Crystallization of this residue was effected by adding three drops of methanol to the ethyl acetate mixture and heating. Filtration and recrystallization from methanol gave 112 mg (0.156 mmole, 90%) of the white crystalline methiodide. Recrystallization from methanol for an analytical sample gave a compound that melted 246–248° dec.

*Anal.* Calcd for  $C_{22}H_{27}IN_2O_8$ : C, 54.70; H, 5.43. Found: C, 54.89; H, 5.47.

**Methyl Deserpideate (IV).** About 100 mg of clean sodium metal was placed into 10 ml of anhydrous methanol. The solution was allowed to stand in ice for 1 hr. Then, 921 mg (1.60 mmoles) of deserpideine in 10 ml of dry methanol was added. The flask was flushed with nitrogen, stoppered, and allowed to stand in the dark at room temperature for 24 hr. The solution had acquired a yellow color. After adding 20 g of ice, the solution was adjusted to pH 6 (Hydriol paper) with dilute hydrochloric acid. The solution was then extracted with three 10-ml portions of ether to remove the methyl 3,4,5-trimethoxybenzoate. The aqueous layer was made basic by adding 5% sodium carbonate and was then extracted with three 10-ml portions of chloroform. The chloroform solution was dried over sodium sulfate and filtered, and the solvent was removed under reduced pressure. The residue that remained weighed 612 mg. This was dissolved in 2 ml of 95% ethanol, and the solution was made acidic by adding hydrochloric acid in ethanol. Crystallization proceeded very slowly. Filtration gave 400 mg (0.96 mmole, 60%) of white crystalline methyl deserpideate hydrochloride, mp 246–247° dec,  $\lambda_{max}^{EtOH}$  221 and 278  $m\mu$  (log  $\epsilon$  4.59 and 3.94).

*Anal.* Calcd for  $C_{22}H_{27}ClN_2O_8$ : C, 63.07; H, 6.50; Cl, 8.46; N, 6.69; O, 15.27;  $2OCH_3$ , 14.97. Found: C, 63.30; H, 6.40; Cl, 8.81; N, 6.55; O, 15.45;  $OCH_3$ , 14.67.

The free base melted at 159–161° dec,  $[\alpha]^{25}_D +8.4^\circ$  (c 1, pyridine),  $\lambda_{max}^{EtOH}$  225 and 280  $m\mu$  (log  $\epsilon$  4.53 and 3.91).

*Anal.* Calcd for  $C_{22}H_{27}N_2O_8 \cdot 0.5 H_2O$ : C, 67.50; H, 6.95; N, 7.16. Found: C, 67.38; H, 6.76; N, 7.36.

Treatment of methyl deserpideate with 3,4,5-trimethoxybenzoyl chloride in pyridine resulted in the formation of deserpideine with unchanged specific rotation and melting point.

**11-Desmethoxytetrahydroalstoniline (VIII).** Deserpideine (2 g, 3.46 mmoles) was refluxed in 90 ml of absolute methanol and 0.2 g of sodium under nitrogen for 2 hr. The solution was acidified with glacial acetic acid and concentrated *in vacuo* to 10 ml, poured into ice water, acidified with HCl, and extracted with ether. From the ether layer, 0.7 g of 3,4,5-trimethoxybenzoic acid methyl ester was obtained. Basification with potassium carbonate and extraction with ether gave 1.2 g of crude product. Crystallization from alcoholic HCl gave 0.7 g (49%) of methyl deserpideate hydrochloride, mp 246–247° dec,  $[\alpha]^{25}_D -46^\circ$  (c 1, methanol).

The mother liquors of the methyl ester hydrochloride crystallization after conversion to the free base were chromatographed over alumina (Merck acid washed) and eluted with benzene followed by benzene with increasing amounts of chloroform. A 50:50 mixture eluted a substance which crystallized as the hydrochloride from absolute alcohol and had a melting point of 237–239° dec,  $[\alpha]^{25}_D +249^\circ$  (50% ethanol–water),  $\lambda_{max}^{EtOH}$  223 and 282  $m\mu$  (log  $\epsilon$  4.70 and 4.02).

*Anal.* Calcd for  $C_{21}H_{21}ClN_2O_8$ : C, 68.38; H, 5.74; Cl, 9.61; N, 7.59; O, 8.68. Found: C, 68.37; H, 5.76; Cl, 9.32; N, 7.40; O, 8.66.

The free base VIII crystallized from ethanol, mp 174–176° dec,  $[\alpha]^{25}_D +288^\circ$  (c 0.5, pyridine), and was susceptible to air oxidation.

*Anal.* Calcd for  $C_{21}H_{21}N_2O_8 \cdot 0.5 C_2H_5OH$ : C, 74.34; H, 6.52; N, 7.88; O, 11.25;  $OCH_3$ , 8.73. Found: C, 74.84; H, 6.52; N, 7.70; O, 11.14;  $OCH_3$ , 9.07.

**Deserpideic Acid (V).** Deserpideine hydrochloride (1.2 g, 1.96 mmoles) in 12 ml of methanol and 6 ml of 10 *N* sodium hydroxide was kept at 45° for 5 hr. The alcohol was then removed under slight vacuum, and the solution was carefully adjusted to pH 4.8 giving 3,4,5-trimethoxybenzoic acid (0.43 g). Acidification to pH 2 with concentrated HCl gave crystals of deserpideic acid hydrochloride (0.5 g, 63%). The salt was recrystallized from water, mp 282° dec,  $[\alpha]_D^{25} - 32.5^\circ$  (methanol). The melting point of deserpideic acid was 224–226° dec,  $[\alpha]_D^{25} - 29^\circ$  (50% methanol–water).

*Anal.* Calcd for  $C_{21}H_{23}ClN_2O_4$ : C, 62.30; H, 6.22; Cl, 8.76; N, 6.92. Found: C, 62.39; H, 6.69; Cl, 8.42; N, 6.84.

**Deserpideic acid Lactone (VI).** Deserpideic acid (2 g, 5.43 mmoles) was kept at room temperature for 24 hr in 25 ml of pyridine and 20 ml of acetic anhydride. The solution was then concentrated *in vacuo* and poured onto ice. The clear solution was made basic with sodium bicarbonate and extracted with chloroform, and the chloroform solution concentrated to incipient crystallization. Filtration and recrystallization from methanol gave deserpideic acid lactone (1.1 g, 58%), mp 159–161° dec,  $[\alpha]_D^{25} - 58^\circ$  (methanol).

*Anal.* Calcd for  $C_{21}H_{21}N_2O_5$ : C, 71.98; H, 6.33; N, 7.99. Found: C, 71.81; H, 6.73; N, 8.24.

**Preparation of Methyl Deserpideate (IV) from Deserpideic Acid (V) and Diazomethane.** A solution of diazomethane in ether was prepared by stirring 1.0 g of Du Pont's EXR-101 (70:30 N,N'-dimethylterephthalamide:white mineral oil) in 10 ml of 50% sodium hydroxide and 50 ml of ether and codistilling the diazomethane with ether. To this ethereal diazomethane solution, a solution of 340 mg (0.924 mmole) of deserpideic acid in 15 ml of ether and 45 ml of methanol was added. The yellow solution was allowed to stand at 0° overnight in a hood. After evaporating the solvent, the methyl deserpideate was removed by adding chloroform to the residue and filtering. The starting acid is insoluble in chloroform. The yield of methyl deserpideate was 87 mg (0.228 mmole, 25%).

**Preparation of Methyl Deserpideate (IV) from Deserpideic Acid (V) and Methanolic Hydrogen Chloride.** To a solution of dry hydrogen chloride in 15 ml of anhydrous methanol 202 mg (0.544 mmole) of deserpideic acid was added. The flask was flushed with nitrogen, stoppered, and allowed to stand at room temperature in the dark for 48 hr. The methanol was evaporated *in vacuo* giving a yellow viscous oil. This oil was extracted with 5% sodium carbonate and chloroform. The chloroform layer was dried, and the solvent was removed giving 185 mg (0.484 mmole, 88%) of an off-white solid whose infrared spectrum and nmr spectrum were identical with those of authentic methyl deserpideate. This product was recrystallized from methanol, mp 159–161° dec.

**Preparation of Methyl Deserpideate (IV) from Deserpideic Acid Lactone (VI).** About 25 mg of fresh sodium was placed into 3 ml of anhydrous methanol. After the sodium had reacted, the solution was cooled to 0°, and 15 mg (0.0428 mmole) of deserpideic acid lactone was added. The flask was flushed with nitrogen, stoppered, and allowed to stand in the dark at 0° for 45 hr. Dry methanolic hydrogen chloride was slowly added to bring the solution to pH 5, sodium chloride precipitating out. The solvent was removed by passing a stream of dry nitrogen over the solution. Chloroform was added to the residue, and the inorganic salts were filtered. The chloroform was evaporated under reduced pressure; the residue was taken up into 5 ml of chloroform, and the solution was washed with two 5-ml portions of 5% sodium carbonate solution. The chloroform layer was dried with anhydrous sodium sulfate and filtered and the solvent removed under reduced pressure. The product from this treatment had melting point and infrared and nmr spectra that were identical with those of authentic methyl deserpideate.

**Hydrogenation of Deserpideine (I).** Exactly 2.86 g (4.96 mmoles) of deserpideine was dissolved in 250 ml of 95% ethanol and added to a mixture of 565 mg of platinum oxide in 10 ml of 95% ethanol. The hydrogenation bottle was flushed with nitrogen and placed on a Parr hydrogenation apparatus and was then charged with 36 lb of hydrogen. Shaking was started and continued for 2 days. The bottle was then removed and thoroughly flushed with nitrogen. The catalyst was filtered from the solution by repeatedly passing the mixture through very retentive, quantitative filter paper (Schleicher and Schuell, Analytical Filter Paper, No. 576) until no catalyst was seen on the filter paper; four times were sufficient. The solvent was removed under reduced pressure giving 2.69 g of yellowish amorphous solid. The hydrogenation product was extracted with aqueous sodium carbonate and chloroform. The aqueous extracts were acidified by the addition of concentrated hydrochloric acid. A white crystalline precipitate formed, which was filtered from the cold

solution giving 723 mg (3.41 mmoles, 69%) of a white crystalline solid, mp 168–170°. This compound was shown to be identical with authentic 3,4,5-trimethoxybenzoic acid by melting point, mixture melting point, and infrared spectrum. The chloroform extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to dryness leaving 1.97 g of a tan amorphous solid. This material was then distributed between ether and 0.5 *M* phosphoric acid. The ether extracts were dried and evaporated leaving 410 mg of a yellow residue. This was the neutral fraction. Addition of ethyl acetate to this fraction caused it to crystallize. After filtration and recrystallization from methanol, 123 mg of white crystalline 16-methyl-19-methoxy-21-oxoyohimbane (X) was obtained, mp 245–247° dec,  $[\alpha]_D^{25} + 142^\circ$  (c 0.8, chloroform). An infrared spectrum showed no absorption between 5.0 and 6.0  $\mu$ . The nmr spectrum showed one methoxyl absorption at  $\delta$  3.25 and a C–CH<sub>3</sub> doublet at  $\delta$  1.03. The mass spectrum exhibited a molecular ion peak at *m/e* 338.

*Anal.* Calcd for  $C_{21}H_{23}N_2O_5$ : C, 74.52; H, 7.74; N, 8.28. Found: C, 74.62; H, 7.84; N, 8.55.

The acidic aqueous layer containing the basic fraction was basified with aqueous sodium carbonate to pH 8 (Hydriol paper) and extracted with ether. The ether extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to dryness leaving 1.39 g of a tan amorphous solid. Addition of ethyl acetate to this material caused it to crystallize. Recrystallization from methanol gave 156 mg of white crystals, mp 224–226° dec,  $[\alpha]_D^{25} - 123^\circ$  (c 0.3, chloroform). This compound had a rate of methiodide formation of  $7.2 \times 10^{-4} \text{ sec}^{-1}$ , characteristics of the epiallo configuration. Its melting point was the same as authentic deserpideine, and a mixture melting point was undepressed. Infrared spectra in chloroform and acetonitrile showed the compounds to be identical. The nmr spectra were superimposable. *R<sub>f</sub>* values in a number of solvent systems also showed their identity: *R<sub>f</sub>* 0.50, chloroform:ethanol:acetone (90:5:5); *R<sub>f</sub>* 0.92, ether:methanol (80:20); *R<sub>f</sub>* 0.63, ether:ethanol (95:5). Finally, both compounds had the same specific rotation,  $[\alpha]_D^{25} - 123^\circ$  in chloroform.

From the mother liquor of the above crystallization, 1.20 g of amorphous material was obtained. A thin layer chromatogram with chloroform:acetone:methanol (80:16:4) as the solvent system showed that the material consisted of at least nine compounds. A preparative scale, thin layer chromatogram was used to purify this mixture, but only one fraction crystallized, mp 266–267° dec, and was shown to be identical with authentic  $\alpha$ -yohimbine methyl ether (XII). The infrared spectra were identical. Thin layer chromatograms showed the two compounds to have the same *R<sub>f</sub>* values in a number of different solvent systems: *R<sub>f</sub>* 0.74, chloroform:acetone:methanol (90:8:2); *R<sub>f</sub>* 0.81, benzene:acetone (80:20); *R<sub>f</sub>* 0.67, benzene:ether (50:50); *R<sub>f</sub>* 0.42, chloroform:acetone (94:6); *R<sub>f</sub>* 0.41, benzene:acetone (90:10); *R<sub>f</sub>* 0.33, benzene:ether (80:20); *R<sub>f</sub>* 0.53, chloroform:ether (80:20).

**Preparation of 16-Methyl-19-methoxyalloyohimbane (XI).** A solution of 25 mg (0.074 mmole) of 16-methyl-19-methoxy-21-oxoalloyohimbane (X) in 50 ml of anhydrous ether was added dropwise to a stirred suspension of 150 mg of lithium aluminum hydride in 50 ml of refluxing ether. After addition was completed, the stirring and refluxing were continued for 12 hr. The excess lithium aluminum hydride was decomposed by the dropwise addition of water, and the inorganic salts were filtered. The ether was evaporated leaving 21 mg (0.065 mmole, 87%) of white 16-methyl-19-methoxyalloyohimbane (XI) that could be recrystallized from either acetonitrile or methanol, mp 217–220° dec. An infrared spectrum showed the disappearance of the band at 6.13  $\mu$ , and the pseudo-first-order rate of methiodide formation was  $2.5 \times 10^{-4} \text{ sec}^{-1}$ , indicative of an allo configuration. The mass spectrum exhibited a molecular ion peak at *m/e* 324 in accord with the molecular formulation  $C_{21}H_{23}N_2O$ .

**Hydrogenation of Methyl Deserpideate (IV).** Platinum oxide (34 mg) in 6 ml of 95% ethanol was reduced by stirring in the presence of hydrogen for 20 min. To this mixture, 66 mg (0.173 mmole) of methyl deserpideate in 11 ml of 95% ethanol was added, and the reaction was allowed to proceed with stirring for 4 days. The mixture was flushed with nitrogen, and the catalyst was filtered (Schleicher and Schuell Filter Paper No. 576). The solvent was removed under reduced pressure leaving 60 mg of an oil. This oil was shown to consist of at least 12 components by thin layer chromatography. An infrared spectrum showed an absorption at 6.12  $\mu$ . Partial separation of the mixture was accomplished by extraction with aqueous hydrochloric acid and chloroform. The chloroform layer (neutral material) was dried and solvent removed under reduced pressure. The residue was crystallized by the addi-

ethanol and yielded 12 mg of white crystalline 16-methyl-19-methoxy-21-oxoalloyohimbane, mp 287–289° dec. The infrared spectrum showed no absorption between 5.0 and 6.0  $\mu$  and a strong amide band at 6.12  $\mu$ . The mass spectrum molecular ion peak at  $m/e$  354.

Calcd for  $C_{24}H_{32}N_2O_4$ : C, 71.16; H, 7.39. Found: C, 71.76.

Aqueous hydrochloric acid fraction was basified by adding sodium carbonate, and this was then extracted with chloroform. Chloroform extracts were dried with anhydrous sodium sulfate, filtered, and the solvent was removed under reduced pressure.

This gave 45 mg of a yellow solid which was subjected to preparative scale thin layer chromatography using chloroform:acetone (60:20:20) as the solvent system. The band value corresponded to authentic methyl deserpidate ( $R_f$  removed). The organic material was eluted from the column by use of hot chloroform and hot methanol. This gave an oil which was once again subjected to preparative scale chromatography using the same solvent system, and again the band was removed. After elution, 10 mg of a white solid was collected. This compound gave an infrared spectrum identical with authentic methyl deserpidate in chloroform and in acetonitrile solution. The nmr spectrum was also with that of authentic methyl deserpidate and different from that of authentic methyl deserpidate. Thin layer  $R_f$  values further established the identity of the two compounds:  $R_f$  0.49, chloroform:methanol (50:20:20);  $R_f$  0.46, ether:methanol (50:50).

**Aluminum Hydride Reduction of 11-Demethoxytetrahydro-13H-benzog[3,4]indolo[2,3-a]quinolizine hydrochloride (VIII).** 11-Demethoxytetrahydroalstoniline hydrochloride (0.135 mmole) was converted to the free base by treatment with aqueous sodium carbonate and ether. The ether was dried over anhydrous sodium sulfate, filtered, and added in a 50-ml addition tube. This solution was added to a stirred suspension of 300 mg of lithium aluminum hydride in 10 ml of ether. After addition was completed (1 hr), the mixture was stirred for 1 hr. Subsequently, 200 mg more of lithium aluminum hydride was added, and the mixture was stirred.

The excess lithium aluminum hydride was decomposed by dropwise addition of water. Sodium sulfate (1 g) was added; the mixture was filtered, and the solvent was evaporated until about half its volume was removed. The hydrochloride was prepared by adding methanolic hydrogen bromide to a solution of the free base. The precipitate was filtered and dried to give 45 mg (0.112 mmole, 83%) of white crystalline 11-demethoxytetrahydroalstoniline hydrochloride (trivial name: 11-demethoxytetrahydroalstoniline hydrochloride) that decomposed without sharp melting around 280°. The infrared spectrum was identical with that of authentic material.<sup>8</sup> Paper chromatography  $R_f$  values in three solvent systems were the same for the two compounds:  $R_f$  0.2, acetic acid:5% sodium acetate (v/v), saturated with water;  $R_f$  0.92, *n*-butyl alcohol saturated with water;  $R_f$  0.1, *n*-butyl alcohol:ethanol, saturated with water.

Calcd for  $C_{20}H_{27}BrN_2O$ : C, 62.34; H, 5.49. Found: C, 62.34; H, 5.62.

**Reduction of 3-Isodeserpideine (VII).** A solution of 576 mg (0.955 mmole) of deserpidine in 10 ml of glacial acetic acid was heated on a steam bath. To this stirring solution, 56 ml of lead tetraacetate in glacial acetic acid was added dropwise over a period of 90 min. The temperature was maintained at 45–50° and the system was kept under a nitrogen atmosphere. The wine red solution was stirred at 45–50° for an additional 1 hr. The acetic acid was then removed *in vacuo*, leaving a red oil. This oil was dissolved in 400 ml of chloroform; 20 ml of water was added and the mixture chilled. To this mixture, sodium hydroxide was added dropwise until the material turned blue on Hydron paper (about 10 ml was needed). The chloroform layer was separated and washed once with 20 ml of water. The chloroform layer was dried over anhydrous sodium sulfate and filtered. It was then made acidic by adding dropwise ethanolic acetic acid, a color change from dark red to orange being observed. The chloroform was removed under reduced pressure leaving a yellow solid (0.955 mmole, 95%) of an orange solid that resisted attempts at crystallization. The infrared spectrum showed absorptions at 9, 3.4, 5.8, 6.1, and 6.3  $\mu$ .

**Reduction of 3-Isodeserpideine chloride (581 mg, 0.955 mmole)** was dissolved in 25 ml of methanol and cooled in an ice bath. Sodium borohydride (676 mg) was added in small portions over a period of 15 min. After 10 min, the dark brown solution

was refluxed for 5 min on a steam bath. Water (70 ml) was added, and the methanol was removed under reduced pressure. The solid was filtered and dried to constant weight (495 mg). This material was dissolved in a minimal amount of chloroform and passed through a 4-in. column of Florisil giving a yellow solution. The chloroform was evaporated leaving a yellow amorphous material that weighed 270 mg. A thin layer chromatogram of this showed it to consist of two compounds which were separated by preparative thin layer chromatography using chloroform:acetone:methanol (90:8:2) as the solvent system. The main component of the reaction was shown to be 3-isodeserpideine (230 mg, 40%). Its rate of methiodide formation was  $31 \times 10^{-4} \text{ sec}^{-1}$  and its infrared spectrum showed the 3-iso bands at 3.4–3.6  $\mu$ .

A solution of 3-isodeserpideine was prepared by dissolving 80 mg (0.138 mmole) of pure 3-isodeserpideine (VII) in 0.5 ml of methanol. This solution was made slightly acidic by the dropwise addition of glacial acetic acid. Eight drops of a saturated ammonium nitrate in methanol solution was then added. A white precipitate formed immediately. This was filtered and recrystallized from methanol giving 73 mg (0.114 mmole, 83%) of white crystalline 3-isodeserpideine nitrate salt, mp 246–249° dec.

Anal. Calcd for  $C_{22}H_{27}N_2O_3$ : C, 60.24; H, 5.83. Found: C, 60.07; H, 5.77.

Exactly 32 mg (0.055 mmole) of 3-isodeserpideine was dissolved in 1.0 ml of ethyl acetate and cooled to 0°. Then, 0.5 ml of pure methyl iodide was added, and the solution was allowed to stand at 0° for 3 days. Crystallization commenced after 6 hr. The solvent was removed under reduced pressure, and the residue was crystallized from methanol. Filtration gave 23 mg (0.032 mmole, 58%) of white crystals of 3-isodeserpideine methiodide, mp 250–253° dec. An analytical sample was prepared by recrystallizing from methanol–water to give white clusters, mp 254–255° dec.

Anal. Calcd for  $C_{22}H_{27}IN_2O_3$ : C, 54.70; H, 5.43. Found: C, 55.02; H, 5.64.

**Hydrogenation of 3-Isodeserpideine (VII).** Exactly 32 mg of platinum oxide in 4 ml of 95% ethanol was reduced to platinum black in a microhydrogenation apparatus. To this mixture 100 mg (0.173 mmole) of 3-isodeserpideine in 7 ml of 95% ethanol was added, and the reduction was allowed to proceed for 15 hr. The catalyst was removed by filtration through very retentive filter paper (Schleicher and Schuell, No. 576), and the ethanol was removed under reduced pressure. A yellow amorphous solid weighing 92 mg remained which was extracted with 5% sodium carbonate and chloroform. The aqueous layer was acidified by adding cold concentrated hydrochloric acid, and a white precipitate formed. Filtration and drying gave 16 mg (64% yield) of a white crystalline compound that was shown to be 3,4,5-trimethoxybenzoic acid by its melting point (168–170°), mixture melting point (undepressed), and infrared spectrum. The chloroform layer was then extracted with dilute hydrochloric acid, and the chloroform layer was dried and evaporated. This left 10 mg of a neutral fraction that showed a amide peak in the infrared at 6.13  $\mu$ . The aqueous hydrochloric acid layer was basified and extracted with chloroform. The chloroform layer was dried and evaporated leaving 62 mg of a yellow solid. Addition of methanol caused crystallization to occur. Filtration and drying gave 12 mg (0.033 mmole, 20%) of a white crystalline material that was shown to be  $\alpha$ -yohimbine methyl ether (XII) by melting point and mixture melting point (266–267° dec) and thin layer  $R_f$  values.<sup>9</sup>

**Hydrogenation of Raujemidine (Ia).** Exactly 39 mg of platinum oxide in 5 ml of 95% ethanol was reduced to platinum black in a microhydrogenation apparatus. To this mixture 200 mg (0.33 mmole) of raujemidine in 12 ml of 95% ethanol was added, and the hydrogenation was allowed to proceed for 72 hr. The catalyst was removed by filtering three times through very retentive filter paper (Schleicher and Schuell, No. 576). The solvent was removed under reduced pressure leaving 190 mg of a yellow amorphous solid. This solid was extracted with 5% sodium carbonate and chloroform. The aqueous phase was acidified with concentrated hydrochloric acid leaving a white precipitate. Filtration and drying of this precipitate gave 25 mg (0.118 mmole, 38%) of a white crystalline solid that was shown to be 3,4,5-trimethoxybenzoic acid by its melting point (168–170°), mixture melting point (undepressed), and infrared spectrum. The organic phase was evaporated and gave a yellow amorphous solid. This was subjected to preparative scale thin layer chromatography using chloroform:ethanol:acetone (90:6:4) as the solvent system and the band whose  $R_f$  values corresponded to reserpine ( $R_f$  0.60) was removed. Elution of the compound from the silica gel and recrystallization of the eluted material gave 19 mg (9% yield) of pure reserpine (IIa) as

shown by infrared and nmr spectra, melting point, and mixture melting point.

**Rate Studies.** The rates of methiodide formation were determined by the method used previously,<sup>8</sup> except for a few minor

changes. Instead of using 10 mg of sample, rates were determined on 3 mg of sample in the present study. The acetonitrile that was used was carefully distilled from CaH<sub>2</sub> and had an observed initial resistance of greater than 1,000,000 ohms.

## Biosynthesis of Methylcyclopentane Monoterpenoids. I. *Skytanthus* Alkaloids<sup>1,2</sup>

H. Auda, H. R. Juneja, E. J. Eisenbraun, G. R. Waller,<sup>3a</sup> W. R. Kays, and

*Contribution from the Departments of Biochemistry, Chemistry, and Horticulture, Oklahoma State University, Stillwater, Oklahoma, and Departamento de Quimica, Universidad Tecnica Federico Santa Maria, Valparaiso, Chile.*

*Received April 23, 1966*

**Abstract:** The biosynthesis of the steam-volatile *Skytanthus* alkaloids has been investigated by administering DL-mevalonate-2-<sup>14</sup>C and L-methionine-methyl-<sup>14</sup>C into the green stems of mature flowing *Skytanthus acutus* M. plants. Radioactivity from mevalonate-2-<sup>14</sup>C was incorporated into the alkaloid. Radioactivity from DL-lysine-2-<sup>14</sup>C was not incorporated, which indicates that lysine is not a precursor. Gas-liquid chromatographic analysis of the alkaloid fraction indicated that the natural oil contains a mixture of which about 90% is  $\alpha$ -,  $\beta$ -,  $\delta$ -, and dehydro-skytanthines. The amounts of these alkaloids vary with the parts of the plant, with roots containing most. Specific activities of the alkaloids derived from mevalonate-2-<sup>14</sup>C and methionine-methyl-<sup>14</sup>C also vary in different parts of the plant. At least four alkaloids of unknown structure which comprise about 10% of natural *Skytanthus* oil were detected. Chemical degradations on micro quantities of alkaloid to eliminate nitrogen and to determine the amount of radioactivity located in carbons 3, 4, 7, 9, and 10 were devised. It was found that L-methionine-methyl-<sup>14</sup>C was the precursor of the N-methyl group of  $\beta$ -skytanthine. The results of biosynthesis experiments using mevalonate-2-<sup>14</sup>C as a precursor provide evidence for the formation of skytanthine isomers *via*: (a) an isoprenoid pathway which involves randomization of the label between the terminal methyl carbon atoms of the monoterpene or monoterpene (*i.e.*, geranyl pyrophosphate) intermediate in 1.3-year-old plants, and (b) an isoprenoid pathway which does not involve randomization of the label between the monoterpene terminal methyl carbon atoms in 3-year-old plants.

Natural oil of *Skytanthus acutus* M. contains a mixture of alkaloids of the rare monoterpene class. At least three skytanthine isomers (Figure 1: Ia, Ib, Id) and a dehydro-skytanthine (II) are produced by *Skytanthus acutus* M.<sup>4,5</sup> *Skytanthus acutus* M. is native to the Atacama desert of Chile and owing to the characteristic shape of its seed pods is commonly referred to as "Goats-horn" by natives of the area. *Skytanthus* alkaloids have no known physiological activity, in contrast to most other methylcyclopentane monoterpene, most of which possess biological activity. The biosynthesis of the *Skytanthus* alkaloids is of interest because they are terpenoid alkaloids<sup>4-9</sup> and

because they may serve as a link to higher alkaloids.<sup>10-13</sup>

The structures of the *Skytanthus* alkaloids suggest that the piperidine nucleus of these molecules could arise from an isoprenoid precursor. The present evidence for the route of formation of the piperidine ring in plants is based largely on studies of the alkaloid biosynthesis of anabasine<sup>14,15</sup> produced by tobacco, homostachydrine<sup>16</sup> by alfalfa, and pipecolic acid<sup>17-20</sup> by various plants and microorganisms. These molecules are derived from lysine. In contrast, the piperidine ring of coniine and conhydrine, which are alkaloids of hemlock, appears to be formed from a poly- $\beta$ -keto acid derived from four acetate units.<sup>21,22</sup> Thus, if the piperidine ring of skytanthine is isoprenoid in origin, a third

ay for the formation of piperidine rings by plants

Leete<sup>23</sup> has recently reviewed the biosynthesis of the piperidine ring.

Results reported in this paper conclusively establish that the skytanthine isomers are of isoprenoid origin and that lysine is not involved in the biosynthesis. The compound was shown to be a precursor of the N-methyl group.

## Experimental Section

**Isolation of Labeled Compounds.** Mature, flowering *Styphelia acuta* M. plants 3 years old were used except for the experiment reported on 1.3-year-old plants. These plants were grown in a greenhouse.

Aqueous solution of the labeled compound was injected into the leaves of a plant. After 4 days the plants were harvested and the leaves, green stems, woody stems, and roots for analysis. The samples were stored in plastic bags at  $-15^{\circ}$  until used.

**Labeled Compounds Used.** Chromatographically pure DL-norleucine-2-<sup>14</sup>C (N,N'-dibenzylethylenediamine salt obtained from Nuclear Research Chemicals, Orlando, Fla., or New England Nuclear Corp., Boston, Mass.), was used.<sup>24</sup> Chromatography was performed using Whatman No. 1 filter paper and 2-propanol-ammonium hydroxide-water (80:5:15) as the solvent. DL-Lysine with a specific activity of 0.6 mcurie/mmol was purchased from Tracerlab-Keleket, Waltham, Mass., and L-methionine-<sup>14</sup>C with a specific activity of 2.25 mcurie/mmol was obtained from Nuclear Research Chemicals, Orlando, Fla. The compounds were radiochemically pure as determined by paper chromatography on Whatman No. 1 filter paper and development with solvent saturated with water and 1-butanol-acetic acid-water (1:1:2).

Measurement of radioactivity was made with a Nuclear-Chicago Model 1000 paper strip scanner.

**Isolation of Steam-Volatile Alkaloids.** The frozen plant segments were cut into 0.5-in. pieces and ground with a mortar and pestle and the pH was adjusted to 10 with 4 N potassium carbonate. The mixture was steam distilled until 300 ml of distillate was collected. The distillate was acidified to pH 2 with concentrated hydrochloric acid and steam distilled. This latter steam-volatile fraction contained the neutral material. The pH of the material in the steam distillation flask was adjusted to 10 with 4 N NaOH and the volatile compounds were steam distilled and collected. The neutral and basic fractions were saturated with sodium chloride and extracted with ether. The ether layers were dried over anhydrous magnesium sulfate, filtered, and concentrated by distillation. The concentrates which remained were each dissolved in a small amount of water and placed in 1-ml volumetric flasks, and stored at  $-15^{\circ}$  until used.

**Chromatography.** Analyses of the alkaloids by gas-liquid chromatography were made on a 0.125 in.  $\times$  10 ft stainless steel column packed with 10% Carbowax 20M on 100-120 mesh base-coated Firebrick. The injector temperature was kept at 160 $^{\circ}$  and the thermal conductivity detector cell at 230 $^{\circ}$ . Peak areas were measured with a disc integrator<sup>25</sup> and the amounts represented were estimated by comparison with standard curves obtained with  $\alpha$ - and  $\beta$ -skytanthine and dehydroskytanthine. The pure compounds were obtained by preparative gas chromatography (0.375 in.  $\times$  10 ft column with the same packing as described above).

**Isotope Analyses.** Carbon-14 activity of the compounds added to the plants, the isolated alkaloids, and the products of chemical degradation of  $\beta$  were determined using dichromatography and/or liquid scintillation counting.<sup>27,28</sup> Gas radiochromatography measurements were performed with a Perkin-Elmer Model 801 gas-liquid chromatograph equipped with a thermal conductivity detector and a Nuclear-Chicago Model 1000 proportional gas flow counter. The total effluent from the column was fed into the counting chamber through a heated inlet

E. Leete, *Science*, **147**, 1000 (1965).

Preliminary experiments indicated that no difference in incorporation of carbon-14 was found when either the free acid or the salt was used as the precursor.

Washed three times with saturated methanolic KOH and once with H<sub>2</sub>O.

Figure 1. Structures of *Skytanthus* alkaloids. The Greek letters refer to isomers of skytanthine.<sup>4,6</sup> II is dehydroskytanthine.

line. The inlet line and the gas counting chamber were held at 250 $^{\circ}$ . Peak areas were measured using a Nuclear-Chicago Model 8350 automatic integrator. The efficiency was 32% as calculated from a reference standard of *n*-heptane-1-<sup>14</sup>C, specific activity 0.25  $\mu$ curie/ $\mu$ mole.

**Chemical Degradation of  $\beta$ -Skytanthine (1 $\beta$ ).** Hofmann Degradation of Skytanthine (1 $\beta$ ) to the Amino Olefin IV. A 2.5-g sample of  $\beta$ -skytanthine (1 $\beta$ ), purified by preparative gas chromatography on a 0.375 in.  $\times$  10 ft column of alkali-treated Chromosorb P coated with 15% Carbowax 20M, was dissolved in 15 ml of absolute ethanol and 5 ml of methyl iodide was added. The mixture was heated at reflux temperature for 6 hr. The reaction mixture was cooled, ether was added to precipitate the methiodide, and the precipitate was filtered out to give 3.5 g of  $\beta$ -skytanthine methiodide, mp 293-295 $^{\circ}$  (lit.<sup>7</sup> 296-298 $^{\circ}$ ). The methiodide, 3.5 g, was dissolved in 200 ml of water and then stirred with freshly prepared silver oxide.<sup>29</sup> The suspension was filtered, and the filtrate was concentrated at 40-50 $^{\circ}$  under vacuum to give 3 g of oil. A 10- $\mu$ l sample of the N-methyl- $\beta$ -skytanthine hydroxide (III) was injected into the alkaline 20M Carbowax column. The injection port, column, and detector temperatures were 200, 123, and 250 $^{\circ}$ , respectively. Two peaks were observed, one corresponding to recovered  $\beta$ -skytanthine (1 $\beta$ ) and the other to the amino olefin IV. The retention times were 16.5 and 12.5 min, respectively. The amino olefin IV was purified by preparative gas chromatography on the alkaline Carbowax 20M column with a yield of about 40%. The infrared spectrum of IV showed bands at 3.26, 6.07, and 11.3  $\mu$ .

**Amine Oxide Degradation of Amino Olefin IV.** A 0.2-g sample of IV was stirred with 1.5 g of 30% hydrogen peroxide for 16 hr until a positive test for base using phenolphthalein was no longer observed. The excess hydrogen peroxide was destroyed by stirring with 24 mg of platinum oxide catalyst until lead sulfide treated paper showed no reaction. The reaction mixture was filtered and concentrated at 30-40 $^{\circ}$  under vacuum and then pyrolyzed. The pyrolysis products were analyzed on the 0.375 in.  $\times$  10 ft alkaline Carbowax 20M column. Peaks were observed for N,N-dimethylhydroxylamine VII (1.8 min), the diene VI (2.3 min), and unreacted IV and I $\beta$ .

**Ozonolysis of Amino Olefin IV.** The amino olefin IV (0.6 g) in ether was dissolved in 10 ml of acetic acid and treated at room temperature for 15 min with oxygen containing ozone. The ozonized solution was transferred to a flask containing a solution of 1 g of ferrous sulfate in 10 ml of water, and the reaction mixture was stirred at room temperature for 30 min, heated for 30 min, and immediately steam distilled into a solution of 0.4 g of dimedon in 100 ml of water. The dimedon derivative was filtered out and crystallized from hot aqueous methanol to give 0.022 g, mp 192-193 $^{\circ}$ . The purity of the dimedon derivative of formaldehyde was tested by thin layer chromatography,<sup>30</sup> using benzene-ethanol-acetic acid (1:1:4) as the solvent system for separation and 2,4-dinitrophenylhydrazine spray solution for detection.

The steam distillation pot residue was cooled, basified with sodium hydroxide solution, and extracted several times with ether. The ether extract was dried over anhydrous sodium sulfate and filtered, and the ether was removed through a fractionating column to give a concentrate containing the amino ketone VIII.

The amino ketone VIII (80 mg) was obtained by preparative gas chromatography, using a 0.375 in.  $\times$  10 ft aluminum column packed with 15% Carbowax 20M loaded on base-washed 60-80 mesh

(29) The silver oxide was prepared from 7.0 g of silver nitrate in 70 ml of water containing 1.7 g of sodium hydroxide by heating the resulting suspension at 85 $^{\circ}$  and washing free of alkali with hot water.

(30) Eastman Kodak Type K301 R Chromatogram sheet.

Chromosorb P. The temperatures of the column, injection port, and detector were 140, 200, and 250°, respectively. A gas pressure of 80 psi at a flow rate of 160 cc/min was used. The retention time of the amino ketone VIII was 31 min. VIII was further purified by thin layer chromatography, using silica gel G in 0.2 N sodium hydroxide solution for coating the glass plates and hexane-acetone-ethanol (4:1:1) as the solvent system with 1% iodine solution in methanol as a detecting spray. The infrared spectrum of VIII showed an absorption peak at 5.85  $\mu$ .

**Peroxytrifluoroacetic Acid Oxidation of Amino Ketone VIII.**<sup>17</sup> Peroxytrifluoroacetic acid was prepared by adding 1.5 ml of trifluoroacetic anhydride to a stirred mixture of 0.4 ml of 90% H<sub>2</sub>O<sub>2</sub> and 7.5 ml of methylene chloride and then stirring at room temperature for 30 min. This product was added dropwise over a period of 5 min to a well-stirred mixture containing 0.6 g of amino ketone VIII in 1 ml of ether and 0.4 g of sodium dihydrogen phosphate in 15 ml of methylene chloride. After addition of the peroxide, the reaction mixture was stirred at room temperature for 30 min and heated at reflux temperature for 1.5 hr. The reaction mixture was cooled and a concentrated solution of sodium sulfite added dropwise with stirring until no more gas was released. Water (10 ml) was then added and stirring continued for 30 min to ensure complete hydrolysis of any excess anhydride. The reaction mixture was basified with sodium hydroxide solution and extracted several times with methylene chloride. The methylene chloride extract was dried over anhydrous magnesium sulfate and filtered and the methylene chloride removed by fractionation to give 0.1 g of the amino acetate IX containing a trace of methylene chloride. The infrared spectrum of the amino acetate IX showed absorption peaks at 5.76 and 8.00  $\mu$ .

**Saponification of the Amino Acetate IX.** The amino ester IX (0.1 g) was added to 1 ml of 20% aqueous sodium hydroxide containing a few drops of methanol. The mixture was heated at reflux temperature for 30 min. The alkaline reaction mixture was cooled and extracted exhaustively with ether. This ether extract was dried over anhydrous sodium sulfate and then distilled to give 50 mg of the amino alcohol X which was purified by thin layer chromatography, using silica gel G in 2% sodium hydroxide solution for coating the glass plates, hexane-acetone-ethanol (2:1:1) as the solvent system, and 1% iodine solution in methanol as a detecting spray. The infrared spectrum of the amino alcohol X showed an absorption peak at 2.95  $\mu$ .

The alkaline residue remaining from the extraction of the amino alcohol X was acidified with 0.5 N sulfuric acid and steam distilled until 50 ml were collected. The steam distillate was neutralized using 0.07 N sodium hydroxide. The 10 mg of sodium acetate obtained on evaporation under reduced pressure was purified by chromatography on a Celite column.

**Kuhn-Roth Oxidation of  $\beta$ -Skytanthine.**<sup>31</sup>  $\beta$ -Skytanthine (1 $\beta$ ) (20 mg) was oxidized with Kuhn-Roth reagent by heating at reflux temperature for 90 min. The reaction mixture was steam distilled until 50 ml was collected, and the steam distillate was neutralized with 0.07 N sodium hydroxide. The 10 mg of sodium acetate obtained on evaporation under reduced pressure was purified by chromatography on a Celite column.

**Preparation of Skytanthine-<sup>14</sup>C Used for Chemical Degradation.** The alkaloids from the methionine-methyl-<sup>14</sup>C biosynthesis experiment were diluted 30-fold with pure  $\beta$ -skytanthine (1 $\beta$ ) and degraded to give amino olefin IV, the diene VI, and dimethylhydroxylamine VII.

$\beta$ -Skytanthine-<sup>14</sup>C formed from mevalonate-2-<sup>14</sup>C biosynthesis experiments was purified by preparative gas chromatography as previously described, diluted two- to fivefold with pure 1 $\beta$ , and degraded as described above. A portion of diluted 1 $\beta$  was degraded using the Kuhn-Roth oxidation procedure.

The specific activity of the diluted alkaloid was redetermined using gas radiochromatography and the liquid scintillation procedures described above.

## Results<sup>32</sup>

**Distribution of Alkaloids.** The distribution of  $\alpha$ -,  $\beta$ -, and dehydroskytanthine in mature *Skytanthus acutus* M. plants is shown in Table I. The roots contained about 5% of the total alkaloids. The  $\beta$  isomer pre-

dominated in all tissues. These three alkaloids constituted about 90% of the total alkaloids isolated. The remaining 10% of the alkaloid fraction was composed of at least four unknown alkaloids and  $\delta$ -skytanthine; the structure of these unknown alkaloids is being investigated. It has been previously reported that natural skytanthine alkaloids are a mixture of three and possibly four diastereoisomers ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ).<sup>4</sup> No  $\gamma$  isomer was found in this study; however, dehydroskytanthine was found in all parts of the plant. Most of the  $\delta$  isomer, which constitutes about 1% of the natural skytanthine alkaloids, was located in the roots.

Table I. Distribution of  $\alpha$ -Skytanthine,  $\beta$ -Skytanthine, and Dehydroskytanthine in Mature *Skytanthus acutus* M. Plants<sup>a,b</sup>

Plant parts	$\alpha$	Skytanthus alkaloids, %	
		$\beta$	Dehydro

<sup>a</sup> Fresh-weight basis. <sup>b</sup> Three-year-old plants.

**Alkaloid Biosynthesis.** The results obtained using DL-lysine-2-<sup>14</sup>C, DL-mevalonate-2-<sup>14</sup>C, and L-methionine-methyl-<sup>14</sup>C are shown in Table II. The  $\alpha$ -,  $\beta$ -, and dehydroskytanthine alkaloids contained 0.56% of the administered carbon-14 from mevalonate-2-<sup>14</sup>C, none from lysine-2-<sup>14</sup>C, and 1.04% from methionine-methyl-<sup>14</sup>C. The incorporation of radioactivity from mevalonate-2-<sup>14</sup>C along with lack of incorporation from lysine-2-<sup>14</sup>C provides evidence that the carbon skeleton of skytanthine arises *via* an isoprenoid precursor rather than a pathway which involves lysine. These results confirm and extend the preliminary report of Casinovi and Marini-Bettolo<sup>33</sup> on the incorporation of radioactivity from mevalonate-2-<sup>14</sup>C into skytanthine produced by sterile excised roots of *Skytanthus acutus* M. A comparison of the specific activities of the skytanthine isomers produced in the various parts of the plant from mevalonate-2-<sup>14</sup>C and methionine-methyl-<sup>14</sup>C shows that the highest values were observed in the alkaloids isolated from the green stems. Most of the carbon-14 in the alkaloids is in the  $\beta$  isomer, which might be expected since it is present in the largest amount. The isotope dilution values, which are readily calculated from the specific activities, indicate that the least dilution occurs in the green stems for all three skytanthine isomers. The distribution of carbon-14 in  $\alpha$ -,  $\beta$ -, and dehydroskytanthine formed from mevalonate-2-<sup>14</sup>C was 13, 53, and 34%, respectively. Corresponding values from the methionine-methyl-<sup>14</sup>C experiment were 9.5, 74.0, and 12.1%. In the methionine-methyl-<sup>14</sup>C experiment 4.4% of radioactivity was found in an unknown alkaloid.<sup>34</sup>

<sup>a</sup> Three-year-old plants.

thine skeleton I was initially established by dehydrogenation to actinidine<sup>7,8</sup> and by partial degradation to the amino olefin IV and the amino ketone VIII.<sup>7</sup>

The existence of three isomers of skytanthine (I $\alpha$ ,  $\beta$ , and  $\delta$ ) in *Skytanthus acutus* M., their structures, and their absolute configurations and stereochemistry were established by comparison with isomers of skytanthine obtained by partial synthesis from the nepetalinic acids of known absolute configuration and stereochemistry.<sup>4,5</sup>

Despite these extensive studies, a nitrogen-free degradation product of skytanthine has not been reported. The reported degradation routes were extended to provide a series of molecules which would reveal location of carbon-14 incorporated into the skytanthine skeleton. The results show that when pure  $\beta$ -skytanthine (I $\beta$ ) is subjected to the Hofmann elimination reaction it is cleanly converted to the previously reported amino olefin IVa.<sup>7,25,26</sup> The choice of the route to be used for complete removal of nitrogen from IVa was then between a second-stage Hofmann or an amine oxide elimination reaction. These methods were compared and both were found to give nitrogen-free diene. The amine oxide elimination from IVa via V was preferred because the resulting diene VI appeared to be a single product, whereas a conventional Hofmann elimination reaction of IVa proceeded to a mixture of dienes possibly having the structures XI and XII. This mix-

ture is to be expected in view of the well-known course of the Hofmann elimination of nitrogen from piper-

(35) Analysis of the methines produced in the reaction was made on the combination mass spectrometer-gas chromatograph (prototype of the LKB-9000) using a 0.25 in.  $\times$  16 ft glass column packed with 20% Carbowax 20M on 100-120 mesh base-washed<sup>24</sup> Firebrick. The column conditions were 200° for injection port, 125° for the column, and a flow rate of 45 cc of He/min. The retention time of IVb was 21 min and that of IVa was 23 min. Quantitative estimation of the relative amounts of each methine was performed by planimetry. IVa comprised over 99% of the mixture.

(36) We are investigating the Hofmann elimination reaction as applied to  $\delta$ -skytanthine (I $\delta$ ) to determine whether stereochemical alteration in the carbon skeleton of the skytanthine isomers affects the direction of elimination and whether more than one olefin is formed.

idine to give piperylene (1,3-pentadiene) rather than 1,4-pentadiene.

The paucity of starting material and lack of knowledge of the structure of skytanthine possibly prevented earlier workers from fully eliminating nitrogen from the skytanthine skeleton. In our hands, this was accomplished without difficulty and procedures (Figure 2) were developed so that complete nitrogen elimination could be carried out on a milligram scale.

The results presented in Table III show the distribution of label in the skytanthine alkaloids formed from L-methionine-methyl-<sup>14</sup>C. When the products of the degradation were analyzed by gas radiochromatography it was found that 47% of the radioactivity was in VI and 26 and 27% of the radioactivity was present as unreacted I and IV, respectively. The diene VI was completely devoid of radioactivity. These results provide conclusive evidence that the N-methyl group of the skytanthine alkaloids originated from the methyl group of methionine.

<sup>a</sup> Three-year-old plants.

**B. Chemical Degradation of  $\beta$ -Skytanthine (I $\beta$ ) to Remove Carbons 3, 4, and 9.** The previously reported degradation<sup>7,8</sup> of the amino olefin IV to the amino ketone VIII and the amino alcohol X was utilized in obtaining techniques to provide suitable derivatives and degradation products for carbon-14 assay to locate the positions of radioactive labeling in I $\beta$ .<sup>26</sup> The ozonolysis of amino olefin IV readily provided the amino ketone VIII and formaldehyde. The latter was isolated as the dimedon derivative, purified by recrystallization and thin layer chromatography to constant specific activity, and then counted to determine the carbon-14

Figure 2. Chemical degradation of  $\beta$ -skytanthine to remove carbons 8, 3, 4, and 9.

Figure 3. Labeling patterns of  $\beta$ -skytanthine biosynthesized by *Skytanthus acutus* plants from mevalonate-2- $^{14}\text{C}$ .

radioactivity at position 3 of  $\text{I}\beta$ . A conventional Baeyer-Villiger oxidation of the amino ketone VIII with peroxytrifluoroacetic acid<sup>37</sup> yielded the expected amino acetate IX which was hydrolyzed to the amino alcohol X and acetic acid. The acetic acid was isolated and used to determine the carbon-14 radioactivity of carbons 4 and 9 of  $\text{I}\beta$ .

The results presented in Table IV show the distribution of the label in  $\beta$ -skytanthine ( $\text{I}\beta$ ) formed from mevalonate-2- $^{14}\text{C}$  using plants of two ages. The data reported in this table are the results of specific activity determinations made using the liquid scintillation method on weighed, purified samples of  $\text{I}\beta$  and its derivatives. Gas radiochromatography experiments (3-year-old plants) on  $\text{I}\beta$ , IV, VIII, and X agree with the results obtained using liquid scintillation counting, but in general these were less reliable because of the low specific activities encountered. The dimedon derivative of formaldehyde and acetate were counted only by the liquid scintillation technique.

A Kuhn-Roth oxidation on the carbon-14-labeled amino alcohol X would provide information on the

(37) W. F. Sager and A. Duckworth, *J. Am. Chem. Soc.*, **77**, 188 (1955).

amount of radioactivity residing in carbons 7 and 10. Because insufficient carbon-14-labeled X was available, this degradation was applied directly to  $\beta$ -skytanthine- $^{14}\text{C}$  which yields acetate representing carbons 7 and 10 and 4 and 9.

**Three-Year-Old Plants.** Results from the chemical degradation indicated that carbon 3 contained 40% of the radioactivity present in the original  $\beta$ -skytanthine- $^{14}\text{C}$  ( $\text{I}\beta$ ). The amino alcohol X and the sodium acetate formed from the amino ketone VIII had 49 and 5% of the radioactivity, respectively (Table IV). Results from the Kuhn-Roth oxidation on the original  $\text{I}\beta$  are shown on the last line of Table IV and indicate that 5% of the carbon-14 resides in carbons 4 and 9 and 7 and 10. These data are interpreted to mean that about 10% of the original radioactivity present in  $\beta$ -skytanthine is present in carbons 4 and 9 and 7 and 10 (Figure 3).

Of the original activity present in  $\beta$ -skytanthine- $^{14}\text{C}$ , 94% (carbons 3, 4, 9, and the amino alcohol X) was recovered in these experiments (Table IV). These results combined with the results of the Kuhn-Roth oxidation of  $\text{I}\beta$  provide convincing evidence for the nonrandomization of the carbon-14 label in  $\beta$ -skytanthine- $^{14}\text{C}$  formed from mevalonate-2- $^{14}\text{C}$ . In addition, a Kuhn-Roth oxidation was performed on  $\alpha$ -skytanthine possessing a specific activity of 9.25  $\mu\text{curies}/\text{mmole}$ . The sodium acetate obtained was found to possess a specific activity of 0.70  $\mu\text{curie}/\text{mmole}$ , which indicates that 7.6% of the radioactivity was located in carbons 4 and 9 and 7 and 10.

**16-Month-(1.3 years)-Old Plants.** The degradation of  $\beta$ -skytanthine- $^{14}\text{C}$  from 1.3-year-old plants yielded entirely different results than were obtained with 3-year-

Distribution of Radioactivity in  $\beta$ -Skytanthine Biosynthetically Formed by *Skytanthus acutus* on Mevalonate-2- $^{14}\text{C}$

Compound	$\beta$ -Skytanthine carbon atom	3 years old		1.3 years old	
		Sp act., $\mu\text{curies/mmole}$	%	Sp act., $\mu\text{curies/mmole}$	%
$\beta$ -Skytanthine (I $\beta$ )	All	8.87	100	5.63	100
Methine (IV)	All	8.7	98	5.70	101
Ketone (VIII)	All but 3	5.1	57	4.25	75.5
HCHO (dimedon deriv)	3	3.5	40	1.37	24.4
Amino alcohol (X)	All but 3, 4, and 9	4.3	49	...	...
Sodium acetate (from VIII)	4 and 9	0.41	5	...	...
Sodium acetate (from I $\beta$ )	4 and 9, also 7 and 10	0.41	5	0.77	13.7

nts (Table IV). Owing to the limited quantity of  $\beta$ -skytanthine- $^{14}\text{C}$ , chemical degradation could not be carried beyond the formation of the amino alcohol (X) and the dimedon derivative of formaldehyde (carbon 3). The results indicate that 24% of the radioactivity is located in carbon 3. Sodium acetate obtained from the Kuhn-Roth oxidation of the  $\beta$ -skytanthine contained about 14% of the radioactivity in the alkaloid. A theoretical value of 15% radioactivity would be expected to be found in sodium acetate if, in the original  $\beta$ -skytanthine- $^{14}\text{C}$ , the radioactivity was located in carbon 9 and carbon 10 (this is assuming that the acetate obtained from the Kuhn-Roth oxidation of I $\beta$  is formed in amounts from carbons 4 and 9 and 7 and 10). On the other hand, if carbons 9 and 10 each contained the radioactivity, then the acetate obtained from the Kuhn-Roth oxidation would be expected to contain 15% of the radioactivity. If these carbons contained the radioactivity present originally, then the acetate obtained would be expected to contain 5% of the radioactivity also. The fact that the acetate contained 14% of the radioactivity provides evidence that one of carbons 9 and 10 contained about 25% and the other contained about 5% of the original radioactivity present in  $\beta$ -skytanthine- $^{14}\text{C}$ . To further support this view, a Kuhn-Roth oxidation of dehydroskytanthine- $^{14}\text{C}$  (obtained from the same biosynthesis experiment) possessed a specific activity of 41.0  $\mu\text{curies/mmole}$  and sodium acetate possessing a specific activity of 6.10  $\mu\text{curies/mmole}$  corresponding to 15% of the radioactivity originally found in II, was obtained. These data and the data shown in Table IV support the conclusion that about 25% of the radioactivity originally present in  $\beta$ -skytanthine- $^{14}\text{C}$  (I $\beta$ ) is located in carbon 9 and that 5% is located in carbon 10 (carbon 3). It would then appear that in the young, growing *Skytanthus acutus* M. plants, randomization of the methyl label from mevalonate-2- $^{14}\text{C}$  at the monoterpenoid level occurs when the two terminal methyl groups were equivalent (i.e., geraniol, geranyl pyrophosphate, or methylcyclopentane monoterpenoid intermediate). A comparison of the different labeling patterns in  $\beta$ -skytanthine- $^{14}\text{C}$  (I $\beta$ ) biosynthesized from mevalonate-2- $^{14}\text{C}$  using 1.3-year-old and 3-year-old *Skytanthus acutus* M. plants is shown in Figure 3.

#### Discussion

It is of interest to compare these results with those obtained by Yeowell and Schmid.<sup>38</sup> Results from A. Yeowell and H. Schmid, *Experientia*, 20, 250 (1964).

chemical degradation of plumieride formed biosynthetically from mevalonate-2- $^{14}\text{C}$  showed that randomization occurred between carbon atoms 3 and 15 (25% of the radioactivity residing in each), and that carbon 7 contained 44%. It can be assumed that

carbon atom 10 would contain about 6% of the radioactivity, which is in agreement with our finding on  $\beta$ -skytanthine. Yeowell and Schmid<sup>38</sup> suggested that randomization might occur after ring closure of the cyclopentanoid ring and that carbon atoms 3 and 15 might be equivalent aldehyde groups. Randomization of the terminal methyl label in the isoprenoid portion of certain indole alkaloids has also been reported,<sup>39-41</sup> and the proposed mechanisms are similar to that suggested for plumieride. These data are also supported by labeling experiments using geranyl pyrophosphate-2- $^{14}\text{C}$ <sup>42,40-43</sup> and geraniol-2- $^{14}\text{C}$ .<sup>42-44</sup> For a review on methylcyclopentane monoterpenoids as intermediates in the biosynthesis of indole alkaloids see Taylor.<sup>12</sup> It seems logical that randomization might occur at the monoterpenoid level in these compounds since carbon 15 of plumieride is further oxidized to a carboxylic acid group and this biological oxidation might be expected to proceed in a stepwise direction involving alcohol, aldehyde, and finally acid. In skytanthine carbon atom 9 (equivalent to carbon 15 of plumieride) remains as a methyl carbon, and the chance for randomization of label via a similar type of intermediate involving methyl groups as carbon atoms 3 and 9 exists at the geraniol or geranyl pyrophosphate state in  $\beta$ -skytanthine biosynthesis. In contrast to the experiments showing the occurrence of randomization, the

results obtained by Birch, *et al.*,<sup>45</sup> from the incorporation of mevalonate-2-<sup>14</sup>C into the terpenoid side chain of mycelianamide indicated that 80% of the radioactivity was not randomized, and it was suggested that the degree of randomization observed was more likely a result of the chemical degradative procedure than of a lack of specificity during biosynthesis. It is possible that the extent of randomization which can occur on the appropriate intermediate (*i.e.*, geranyl pyrophosphate) is subject to control at the enzyme level and by the pool size of the substrate. Insufficient knowledge exists on both of these points to permit a definite conclusion.

There may be several possible types of enzymatic control. For example, different enzyme inhibitors or different levels of enzyme may be present in the old and young plants. Also, it may be possible that the particular enzyme responsible for randomization of the monoterpenoid intermediate does not exist in the old plant. An analogous situation is known to occur in the rapid appearance and disappearance of diamine oxidase in pea seedlings.<sup>46</sup> Control by the substrate pool size can best be visualized by considering that the young plant has a rather large pool of monoterpenoid intermediate and that the two terminal methyls become equivalent. In the old plant perhaps only a small pool of monoterpenoid intermediate exists, and this substrate is immediately utilized in the biosynthesis and does not remain long for randomization of the methyl carbons to occur.

An alternative explanation, although remote, to the finding of randomization of label in the 1.3-year-old plant is the possibility of incorporation of mevalonate-

U-<sup>14</sup>C which has been formed by degradation of the administered mevalonate-2-<sup>14</sup>C to <sup>14</sup>CO<sub>2</sub> which, in turn, is reincorporated *via* CO<sub>2</sub> fixation. The results recently reported by Battu and Youngken<sup>47</sup> suggest that degradation of mevalonate to CO<sub>2</sub> and reincorporation of the latter into monoterpenes of *Mentha piperita* can occur.

Our data also support the mechanism of isomerization of isopentenyl pyrophosphate proposed first by Agranoff, *et al.*,<sup>48</sup> and later established by Shah, *et al.*<sup>49</sup> In this mechanism, the methylene carbon atom of isopentenyl pyrophosphate is protonated, the proton from carbon atom 2 is discharged into the medium, and dimethylallyl pyrophosphate is formed. In the reverse reaction, a proton is added stereospecifically at carbon atom 2 of dimethylallyl pyrophosphate. Hence this isomerization does not result in a randomization of label originally present in the methylene group of isopentenyl pyrophosphate.

The metabolic relationship of mevalonate-2-<sup>14</sup>C and  $\beta$ -skytanthine-<sup>14</sup>C (1 $\beta$ ) in 1.3-year-old plants and 3.0-year-old plants has been examined and this compound has been implicated in the biosynthesis of skytanthine by *Skytanthus acutus* M. The pathway for the biosynthesis of skytanthine isomers is not well understood. The contrast in our finding of randomization of label in  $\beta$ -skytanthine formed from mevalonate-2-<sup>14</sup>C in 1.3-year-old plants with that of nonrandomization of label in 3.0-year-old plants requires additional study before its significance can be determined. Variation in an enzymatic reaction mechanism due to age appears to be a new phenomenon.

## Communications to the Editor

### Reactions of Vapor-Produced *t*-Butyl Carbonium Ion Injected into Liquid Isobutylene

Sir:

The reactions of specific, highly reactive hydrocarbon ions in the liquid phase are difficult to study directly. Ions may be produced in the liquid by direct liquid radiolysis, but the situation is complicated because many other reactive species such as electrons, radicals, and excited molecules are produced simultaneously. This complex situation may be simplified by producing specific ions in the vapor phase and injecting them by means of an electric field into a liquid or solid matrix. Under such conditions the positive ion is separated from its concomitant electron and is accelerated into the liquid or solid alone. To achieve this we describe a successful experimental method which is based on previous experiments by Schlag and Sparapany.<sup>1,2</sup>

(1) E. W. Schlag and J. J. Sparapany, *J. Am. Chem. Soc.*, **86**, 1875 (1964).

(2) J. J. Sparapany, *ibid.*, **88**, 1357 (1966).

By this method we have studied the liquid phase reaction of *t*-butyl carbonium ion with isobutylene to form C<sub>8</sub> carbonium ions and their subsequent neutralization reactions.

The apparatus has been described.<sup>3</sup> A krypton resonance lamp<sup>4,5</sup> with intensity of greater than 10<sup>15</sup> quanta/sec ionizes research grade isobutylene in the vapor phase. An electric field at right angles to the photon beam drives the positive ions into a detachable arm containing liquid isobutylene. The liquid arm of the cell extends into a dewar and is thermostated with a cold nitrogen gas stream; the temperature may be varied by changing the flow rate. A voltage of 400 v was applied to the external electrodes during photolysis. At -128° the per cent conversion of isobutylene was linear beyond 120 min of photolysis time; the conversion rate was 0.01%/min. Gas chromatography showed

that  $C_8$  and  $C_{12}$  compounds comprised all detectable products; no products between  $C_8$  and  $C_{12}$  were observed. Material balance calculations showed that the  $C_8$  and  $C_{12}$  compounds detected constituted over 95% of the reacted isobutylene. In several experiments the polarity of the electric field was reversed. With reversed polarity no products were observed; also, direct photolysis of isobutylene vapor at 5 torr produced no detectable  $C_8$  or  $C_{12}$  products. These results support our contention that the positive ions are reacting in the liquid phase.

The  $C_8$  products were analyzed on a  $AgNO_3$ -benzyl cyanide gas chromatographic column, which discriminates between alkenes and alkanes, and on an SE-30 column, which discriminates according to boiling point. The compounds were identified by retention-time comparison on both columns with  $C_8$  standards from Chemical Samples Co., and identification was confirmed in part by mass spectrometry. Table I summarizes the products found at  $-128^\circ$ ; it will be seen that the individual  $C_8$  isomers reveal the probable structure of the  $C_8$  carbonium ions and how they are neutralized.

**Table I.** Relative Yields of  $C_8$  and  $C_{12}$  Products from  $t-C_4H_9^+$  Reaction with Liquid Isobutylene<sup>a</sup>

Product	Yield, %
Relative Total Products	
$C_8$ products	$73 \pm 6$
$C_{12}$ products	$27 \pm 4$
Relative $C_8$ Products	
2,2,4-Trimethylpentane	$4.5 \pm 1.0$
2,4,4-Trimethylpentene-2	$48.4 \pm 4.8$

3,4,4-Trimethylpentene-2	$27.3 \pm 3.8$

<sup>a</sup> 120-min photolysis,  $-128^\circ$ .

The krypton resonance lamp emits photons at 1236 Å (10.0 eV) and 1165 Å (10.6 eV) with relative intensities of 1.00 and 0.28, respectively.<sup>6</sup> The ionization potential of isobutylene is 9.4 eV, and the lowest appearance potential for a fragment ion from isobutylene is 11.3 eV ( $C_4H_7^+$ ).<sup>7</sup> Therefore the only ion produced is the parent  $C_4H_9^+$ . Under our experimental pressure (0.05 torr) and nominal electric field (70 v/cm), we calculate that the  $C_4H_9^+$  ion will make one or two collisions with isobutylene to form mainly  $t-C_4H_9^+$  as shown by mass spectrometry<sup>8-10</sup> before reaching the liquid. The electron released may gain sufficient energy in the electric field to cause ionization and fragmentation. However, variation of the nominal electric field produces no change in product distribution, so such electron fragmentation does not seem to be significant. We conclude that most of the ions striking the liquid are  $t-C_4H_9^+$  with some unreacted  $C_4H_9^+$  also present.

$t-C_4H_9^+$  can react with the two double-bonded carbons in isobutylene. Reaction with the terminal carbon in isobutylene gives a 2,2,4-trimethylpentyl carbonium ion. This yields the correct carbon skeleton for the major product. There are two basic neutral-

ization reactions for the  $C_8$  carbonium ions: one is hydride transfer to the carbonium ion to yield an alkane plus  $C_4H_7^+$ , and the other is proton transfer from the carbonium ion to give an alkene plus  $C_4H_9^+$ . Both the 2,2,4 alkene and alkane are observed, but their relative abundances show that proton transfer predominates by 10:1. This selectivity is probably associated with the stability of the product  $C_4H_9^+$ ; it also demonstrates that we can obtain relative rates of ion-molecule reactions in certain liquids.

The other two  $C_8$  products indicate somewhat surprisingly that  $t-C_4H_9^+$  also reacts at the tertiary carbon in isobutylene. This yields a 2,2,3,3-tetramethylbutyl primary carbonium ion which is expected to rearrange rapidly to give the tertiary 2,2,3-trimethylpentyl structure. Proton transfer from and hydride transfer to this carbonium ion lead to the observed 3,4,4 alkene and 2,2,3 alkane, respectively. For this carbonium ion the results show that proton transfer again predominates, but only by 2:1.

It is interesting to point out that the total reactivity of  $t-C_4H_9^+$  at both the primary and tertiary carbons in isobutylene is about 50%. Since  $t-C_4H_9^+$  shows so little selectivity in this situation, it may well be excited. We are presently studying the effects of electric field and temperature to gain more insight into this possibility. We are also investigating other liquid-phase ion-molecule reactions by this new technique.

## Evidence for Trapped Dielectrons in Ice

Sir:

Electrons produced by  $\gamma$  radiation are trapped in hydroxide ices at 77°K. The trapped electron,  $e_t^-$ , is characterized by an epr singlet at  $g = 2.001$ ,<sup>1</sup> a broad absorption band with a maximum at 5850 Å,<sup>2</sup> and a hydroxide anion vacancy trapping site.<sup>3</sup> We have found that at high radiation doses  $e_t^-$  reacts to form a diamagnetic species which we believe to be best described as a dielectron,  $e_2^{2-}$ , or two electrons trapped in the same hydroxide anion vacancy.

Frozen solutions of 10.0 and 6.0 M NaOH were  $\gamma$  irradiated at 77°K with  $Co^{60}$ . The yields of  $e_t^-$  and  $O^-$  were measured by epr under conditions where power saturation was absent. The results as a function of radiation dose are shown in Figure 1.

The  $e_t^-$  yield saturates at about 2 Mrads in both 6 and 10 M NaOH, and the saturation yield in 6 M NaOH is proportionately less than in 10 M NaOH. The striking result is the decrease in the  $e_t^-$  yield above 8 Mrads; the optical absorption band shows a similar decrease. Since the  $O^-$  yield continues to increase over the entire dose range, and since no new para-

Figure 1. Relative  $e_t^-$  and  $O^-$  yields as a function of  $\gamma$  radiation dose in alkaline ices at 77°K.

magnetic species are observed, the  $e_t^-$  must react above 8 Mrads with a species other than  $O^-$  to form a diamagnetic species.

A plausible explanation for the dose saturation behavior is suggested by considering reactions which can compete with the trapping reaction for radiation-produced mobile electrons,  $e_m^-$ . The trapping reaction is shown by (1) where T denotes an available trap for  $e_m^-$ , and possible competing reactions for  $e_m^-$  are given by (2) and (3).

From the dose saturation data for 6 and 10 M NaOH, it is seen that the number of traps available in the system is proportional to  $[OH^-]$ . Reaction 3 involving the radiation-produced hole,  $(H_2O)^+$ , predicts that the dose saturation yield should be independent of  $[OH^-]$  and that the dose at which saturation occurs should depend on  $[OH^-]$ . Neither prediction is observed experimentally, so reaction 3 does not explain the results.

The formation of  $e_{2t}^{2-}$  by reaction 2 is consistent with our results. The onset of dose saturation occurs when a specific fraction of the available traps are filled; hence it is independent of  $[OH^-]$ . At low doses,  $k_1[T] \gg k_2[e_t^-]$ ; saturation occurs when  $k_1[T] = k_2[e_t^-]$ ; and for  $k_2 > k_1$ ,  $[e_t^-]$  decreases at high doses.

In an  $e_{2t}^{2-}$  center we expect that the second electron would be bound more weakly than the first electron. In this case thermal dissociation could lead to  $e_{2t}^{2-} \rightarrow e_t^-$ . We searched for this reaction by warming colorless spheres of 10 M NaOH that had been irradiated to 15 Mrads at 77°K and showed no epr spectrum due to

$e_t^-$ . Above 120°K a blue color was observed to appear; this was trapped by suddenly recooling to 77°K. Both the epr line and optical band of  $e_t^-$  were then observed for the warmed samples. We believe this experiment conclusively demonstrates the existence of  $e_{2t}^{2-}$ .

The direct analogy of  $e_{2t}^{2-}$  in hydroxide ices is the  $F'$  center in irradiated alkali halides.<sup>4</sup> The  $F'$  center consists of two electrons trapped in the same halide ion vacancy; it is diamagnetic, has broad optical absorption in the near-infrared, can be thermally dissociated to yield the F center which is analogous to  $e_t^-$ , and can be produced by optical bleaching of the F center. Symons and co-workers<sup>5</sup> have studied optical bleaching of  $e_t^-$  and indeed find a new, broad absorption in the near-infrared, although no maximum could be observed. This observation is additional evidence for  $e_{2t}^{2-}$ .

The binding of two electrons in the same anion vacancy can be understood qualitatively as follows. The wave function of  $e_t^-$  extends over a greater volume than that of the  $OH^-$  which it replaces; consequently, there will be a small potential well in the  $e_t^-$  volume which can bind a second electron. This argument implies that the second electron is bound more weakly than the first. Vinetskii and Gitterman<sup>6</sup> have calculated the interaction of two electron centers in a dielectric medium. They find a minimum in the potential curve at an  $\sim 4$ -Å separation between the two electrons. The radius of the  $e_t^-$  charge distribution has been previously estimated as 3–4 Å from experimental data.<sup>3</sup> Hence the existence of  $e_{2t}^{2-}$  seems compatible with the approximate theoretical calculations.

## Molecular Orbital Symmetry Conservation in Transition Metal Catalyzed Transformations

Sir:

Woodward and Hoffmann have published a series of communications extending simple molecular orbital theory into the area of reaction chemistry.<sup>1</sup> This

(1) (a) R. B. Woodward and R. Hoffmann, *J. Am. Chem. Soc.*, 87, 395, 2511, 4389 (1965); (b) *ibid.*, 87, 2046 (1965); (c) *ibid.*, 87, 4388 (1965); (d) see also H. C. Longuet-Higgins and E. W. Abrahamson, *ibid.*, 87, 2045 (1965); and K. Fukui, *Tetrahedron Letters*, 2009 (1965).

fresh approach to understanding reacting systems underlines a fundamental concept which correlates, with respect to symmetry, the molecular orbitals of reactants with those of products. The Woodward-Hoffmann postulate, dividing molecular transformations into "allowed" and "forbidden" categories, has proven a powerful tool for understanding a large body of complex chemistry. This communication extends the concept of symmetry conservation into transition metal catalysis.

Bicyclo[2.2.1]hepta-2,5-diene undergoes smooth dimerization to cyclobutane derivatives in the presence of zerovalent Fe,<sup>2</sup> Ni,<sup>3a-c</sup> and Co<sup>4</sup> catalysts, and tetracyclo[2.2.1.0<sup>2,6</sup>.0<sup>3,5</sup>]heptane (quadricyclene) has recently been reported to undergo a facile valence isomerization to bicyclo[2.2.1]hepta-2,5-diene catalyzed by various noble metal complexes.<sup>5</sup> Since, in the metal-free system, a mechanism involving a concerted molecular transformation in these reactions is strictly forbidden by the Woodward-Hoffmann rules,<sup>1b</sup> the role of the transition metal catalysts invites examination.

The concerted fusion of two olefins to a ground-state cyclobutane ring requires the introduction of two electrons into the olefin AS orbital and the removal of two electrons from the olefin SA orbital (A = anti-symmetric; S = symmetric).<sup>1b</sup> A transition metal system containing d orbitals of sufficient energy and possessing the appropriate number of d electrons can, conceivably, carry out these operations. We propose a mechanism for metal-catalyzed cycloaddition in which the metal orbitals combine with the olefin orbitals, giving a set of occupied molecular orbitals of the symmetry required for an allowed reaction path.

Consider the metal-diolefin complex I. For the

concerted cyclobutane, the elements of symmetry are the ZX and YZ planes. The symmetry classifications of the  $\pi$ -orbital combinations of I ( $C_{2v}$ ) are the same as those reported for the uncatalyzed reaction.<sup>1b</sup> These orbitals interact with combinations of metal atomic orbitals as follows: SS ( $a_1$ ) with metal s,  $p_z$ ,  $d_{z^2}$ , and  $d_{x^2-y^2}$ ; SA ( $b_1$ ) with metal  $p_x$  and  $d_{xz}$ ; AS ( $b_2$ ) with metal  $p_y$  and  $d_{yz}$ ; AA ( $a_2$ ) with metal  $d_{xy}$ . Metal orbitals of the appropriate energy could combine with the olefin orbitals yielding a set of new molecular orbitals of the same symmetry classification; bonding between the metal and the olefin, then, could result with electronic population of the bonding molecular orbitals.

(5) H. Hogeveen and H. C. Volger, *ibid.*, 89, 2486 (1967).

Figure 1.

A correlation diagram for the cyclobutane of the ligand-bound olefins is illustrated in Figure 1, which describes an orbital pathway for the placement of electron pairs into the cyclobutane  $\sigma$  bonds and for the removal of the appropriate olefin  $\pi$  electrons. In this process, the electron density in the AS and SA orbitals of the complex is redistributed; in the AS orbital, electron density shifts into the incipient cyclobutane  $\sigma$  bond while in the SA orbital, electron density is localized in the metal  $d_{xz}$  orbital. This can be envisaged as a change in ligand-to-metal bonding as the system moves across the reaction coordinate. Ring closure draws the olefin SA combination sharply upward in energy, thereby diminishing the ligand-to-metal orbital mixing and increasing the electron density in the  $d_{xz}$  orbital. The olefin AS orbital, rehybridizing to a  $\sigma$  bond, undergoes an increase in electron density with diminished metal  $d_{yz}$  orbital mixing. An electronically excited product can conceivably result depending on the nature and geometry of the metal system, but, given the general ordering of orbitals pictured in Figure 1, a reaction path to a ground-state cyclobutane ligand exists. This simple description is supported by extended Hückel molecular orbital calculations<sup>6</sup> carried out on the cyclobutane of two olefin ligands attached to nickel dicarbonyl, a system reported to cyclobutane bicyclo[2.2.1]hepta-2,5-diene.<sup>3a</sup> The calculations yielded correlation diagrams describing the allowed transformation.<sup>7</sup>

Other transition metal catalyzed reactions suggest metal participation of this sort. The nickel-catalyzed conversion of acetylene to cyclooctatetraene, the Reppe synthesis,<sup>8</sup> is an example. In a close examination of this reaction, Schrauzer has favored a concerted mechanism in which the four  $\sigma$  bonds of the cyclooctatetraene are formed essentially simultaneously.<sup>9</sup> Since the isolated transformation is thermally forbidden,<sup>1b</sup> such a mechanism suggests the electronic participation by the metal. The molecular orbital symmetry aspects of this reaction were examined using as a model the structure II proposed by Schrauzer.<sup>9</sup>

The four  $\pi$  orbitals of the acetylene ligands in II can be treated as two sets, each containing a pair of

(9) G. N. Schrauzer, *Angew. Chem. Intern. Ed. Engl.*, 3, 185 (1964).

Figure 2.

$\pi$  orbitals (Figure 2). The ligands seated at the corners of  $\sigma_2$  comprise set 1 and the ligands positioned on the edges of  $\sigma_1$  constitute set 2. The members of each set

interact yielding the following combinations. Orbitals in set 1 will interact with orbitals in set 2 of the same symmetry yielding a new set, half the members of which are bonding in the region of space between the sets and the other half antibonding. The SS and SS orbitals, for example, combine giving two orbitals, both of SS symmetry, one bonding in the region of the incipient cyclooctatetraene  $\sigma$  bonds and the other antibonding in that region. The four bonding members of the final set correspond in symmetry to the incipient  $\sigma$  bonds of cyclooctatetraene. If the interaction between the orbitals of the metal system and the olefin combinations results in the electronic population of these four molecular orbitals, then an orbital pathway to the concerted cycloaddition exists.

The application of symmetry conservation concepts to the selected reactions<sup>10</sup> introduces a novel mechanism involving a role for the transition metal unique in catalysis. The results suggest that certain metal systems containing orbital configurations of the prerequisite energy are capable of rendering otherwise forbidden cycloaddition reactions allowed by providing a template of atomic orbitals through which electron pairs of transforming hydrocarbon ligands and metal systems can interchange and flow into the required regions of space.

**Acknowledgment.** We are grateful to Drs. J. Merritt, F. S. Mortimer, Isaac Dvoretzky, and J. H.

(10) Electronic involvement by a transition metal is suggested in other systems. The cobalt-catalyzed isomerization of allylbenzene to  $\beta$ -methylstyrene is an example.<sup>11</sup> Back donation of d electrons converts the suprafacial [1,3] sigmatropic change of order<sup>10</sup> to an allowed process.

## Valence Isomerization of Quadricyclene<sup>1a</sup> to Norbornadiene<sup>1b</sup> Catalyzed by Transition Metal Complexes

Sir:

The thermal isomerization of quadricyclene (I) to norbornadiene (II) is known to proceed slowly ( $t_{1/2} > 14$  hr at  $140^\circ$ ).<sup>2</sup> It has now been found that the rate of this reaction is dramatically increased by transition metal-olefin complexes. For instance,  $t_{1/2}$  at  $-26^\circ$  was found to be 45 min for a 0.7 M solution of I in  $\text{CDCl}_3$  in the presence of 2 mole % of di- $\mu$ -chloro-bis-(bicyclo[2.2.1]hepta-2,5-diene)dirhodium(I).

Complexes such as di- $\mu$ -chloro-tetrakis(ethylene)dirhodium(I), dichloro(1,5-cyclooctadiene)palladium(II), di- $\mu$ -chloro-bis( $\pi$ -methallyl)dipalladium(II), and dichloro(bicyclo[2.2.1]hepta-2,5-diene)platinum(II) behave similarly. For all complexes a quantitative conversion of I into II was observed. The isomerization catalyzed by di- $\mu$ -chloro-bis(bicyclo[2.2.1]hepta-2,5-diene)dirhodium(I) was followed kinetically by integration of the olefinic triplet ( $\delta$  6.82 ppm) in the nmr spectrum of the norbornadiene formed. The samples were prepared at about  $-60^\circ$  in  $\text{CDCl}_3$ , warmed up rapidly to the desired temperature, and then transferred to the cavity of the nmr spectrometer (being at the same temperature).

The reaction proved to be first-order in quadricyclene and, as shown in Table I, about first order in catalyst.

**Table I.** Pseudo-First-Order Rate Constants of the Reaction<sup>a</sup> Quadricyclene  $\rightarrow$  Norbornadiene

$[\text{Rh}_2(\text{norbornadiene})_2\text{Cl}_2]$ , M	$10^2 k$ , sec <sup>-1</sup>
0.02	0.025
0.06	0.068

<sup>a</sup> At  $-26^\circ$ ; [quadricyclene] = 0.7 M ( $\text{CDCl}_3$ ).

The apparent values of the activation parameters (inaccurate because of experimental difficulties, such as temperature control and instability of the catalyst solution) are  $\Delta H^\ddagger = 21 \pm 5$  kcal mole<sup>-1</sup>,  $\Delta S^\ddagger = 45 \pm 18$  eu (catalyst concentration 0.036 M).

The mechanism of the reaction is thought to involve a coordination of quadricyclene to the transition metal either *via* an exchange with the originally coordinated olefin or by extension of the coordination around the metal. For the rhodium-olefin complexes and for the

(1) (a) IUPAC designation tetracyclo[3.2.0.0<sup>2,7</sup>.0<sup>4,6</sup>]heptane; (b) IUPAC designation bicyclo[2.2.1]hepta-2,5-diene.

(2) G. S. Hammond, N. J. Turro, and A. Fischer, *J. Am. Chem. Soc.*, **83**, 4674 (1961).

$\pi$ -allyl-palladium complex coordination is possible with either the binuclear or the mononuclear species. This coordination of quadricyclene (I) may well be due to the  $\pi$  character of the cyclopropane bonds common to the three- and four-membered rings.<sup>3</sup>

The valence isomerization I  $\rightarrow$  II described is, by the Woodward-Hoffmann rule for cycloadditions,<sup>4</sup> thermally forbidden. The catalysis observed might well be caused by the presence in the complex of occupied molecular orbitals with symmetries that make the isomerization an allowed process.<sup>5</sup>

### The 7-Norbornyl Cation

Sir:

The nature of the cation formed in the solvolysis of 7-tosyloxybicyclo[2.2.1]heptane (1) has not been clearly established. Winstein and co-workers have described the ionization of 1 as an "example of carbon participation in solvolysis" in which the delocalized ion, 2, is formed.<sup>1</sup> In contrast, Foote<sup>2</sup> and Schleyer<sup>3</sup>

have used the solvolysis of 1 as an example of a system which solvolyzes without anchimeric assistance.<sup>4</sup>

We have found that solvolysis of *exo,exo*-2,3-dideuterio-*anti*-tosyloxybicyclo[2.2.1]heptane (3), in acetic acid buffered with sodium acetate, gave the mixture of products previously reported in the literature.<sup>1</sup> Isolation of the 7-acetoxibicyclo[2.2.1]heptane, which constituted greater than 90% of the reaction product, provided a mixture of deuterium labeled compounds. Infrared analysis *vs.* standard mixtures showed that the solvolysis product consisted of  $90 \pm 3\%$  of 4 and  $10 \pm 3\%$  of 5.

Both the tosylate, 3, and the acetate, 4, were prepared from 6. The synthesis of 6 involved dideuteriodiimide<sup>5,6</sup> reduction of *anti*-7-hydroxybicyclo[2.2.1]heptene.<sup>7</sup> The acetate, 5, was synthesized from 7, which

(1) S. Winstein, F. Gadiant, E. T. Stafford, and P. E. Klinedinst, Jr., *J. Am. Chem. Soc.*, **80**, 5895 (1958).

(2) C. S. Foote, *ibid.*, **86**, 1853 (1964).

(3) P. Schleyer, *ibid.*, **86**, 1854, 1856 (1964).

(4) It is assumed in this paper that anchimeric assistance and participation of neighboring groups are interrelated phenomena. For discussion of this relationship see P. Bartlett, "Nonclassical Ions," W. A. Benjamin, Inc., New York, N. Y., 1965, and J. Berson, "Molecular Rearrangements," Vol. 1, P. de Mayo, Ed., Interscience Publishers, Inc., New York, N. Y., 1963, Chapter 3.

(5) We wish to thank Professor J. Berson for providing us with experimental details for dideuteriodiimide reductions.

(6) The acetate prepared from 6 was shown to contain 90% of the theoretical amount of deuterium. All deuterium analyses were performed by J. Nemeth, Urbana, Ill.

(7) S. Winstein, M. Shatavsky, C. Norton, and R. B. Woodward, *J. Am. Chem. Soc.*, **77**, 4183 (1955); S. Winstein and M. Shatavsky, *ibid.*, **78**, 592 (1956).

had been prepared *via* diimide reduction of the known<sup>8</sup> *exo,exo*-2,3-dideuterio-*syn*-7-hydroxybicyclo[2.2.1]hept-5-ene.<sup>9</sup> In order to ascertain that the dideuteriodiimide reduction occurred from the *exo* side, both 6 and 7 were oxidized to the same ketone, 8. Whereas the ketones obtained from 6 and 7 were identical in all respects, the infrared and nmr spectra of each member of the epimeric pairs, 6 and 7, 4 and 5, and 3 and 9, were different.

We propose that the large degree of retention of configuration observed in the solvolysis of 3 is most consistent with concerted participation of the 1,2  $\sigma$  electrons to form the delocalized ion, 10. Unlike certain explanations of the formation of the 2-nor-

bornyl cation,<sup>10</sup> the formation of 10 may not be postulated to proceed *via* an initially formed classical ion such as 11 since, if 11 were an intermediate, approximately equal amounts of 4 and 5 should be formed.<sup>11</sup> Thus, it appears likely<sup>12</sup> that concerted ionization and carbon participation occur in the acetolysis of 3.

(8) B. Franzus and E. I. Snyder, *ibid.*, **87**, 3423 (1965).

(9) A tosylate, 9, prepared from 7, was shown to contain 95% of the theoretical amount of deuterium.

(10) It has been suggested that the initial step in the solvolysis of 2-tosyloxybicyclo[2.2.1]heptane is formation of a classical carbonium ion at C-2 of the bicyclo[2.2.1]heptyl system. For a discussion of this point of view see H. C. Brown, "The Transition State," Special Publication No. 16, The Chemical Society, London, 1962.

(11) It is assumed that the steric requirements of deuterium *vs.* hydrogen would not be sufficiently different to cause the observed product distribution.

(12) An alternate rationalization of the observed results would invoke a front-side displacement on the ion pair by solvent. Indeed, Brown has suggested<sup>13</sup> the possibility "that even static classical ions, where the structure inhibits approach from the back side, may well undergo substitution with retention." Obviously, special classes of molecules, such as bridgehead tosylates where back-side approach is impossible, can only solvolyze with retention.<sup>14</sup> However, we doubt whether the tosylate, 3, can be justifiably classified as one in which solvent approach from the back side is hindered to the extent that the mechanism of acetolysis becomes one of "front-side displacement." In the absence of such steric hindrance to back-side approach of solvent we see no obvious reason for suggesting front-side displacement of solvent on any ion pair derived from 3.

The occurrence of *ca.* 10% of the inverted product 5 merits comment. Two reasonable possibilities exist for the formation of 5. A direct displacement of tosylate ion by acetic acid with inversion of configuration at C-7 could account for the presence of 5. Alternately, 10 could be "leaking" to the classical ion 11 which would then be partitioned between 4 and 5. Precedent for this latter type of interconversion has been noted in the bicyclo[2.2.2]octyl system.<sup>15</sup> Experiments aimed at distinguishing between these two possibilities are in progress.

**Acknowledgment.** This investigation was supported by a grant from the Petroleum Research Fund administered by the American Chemical Society.

### Retention of Configuration in the Solvolysis of 2,3-Dideuterio-7-norbornyl *p*-Bromobenzenesulfonate

Sir:

Acetolysis and formolysis of *anti*-2,3-dideuterio-7-norbornyl *p*-bromobenzenesulfonate (Ia)<sup>1</sup> proceed with predominant retention of configuration. Therefore,

Figure 1. Nmr spectra of *anti*-2,3-dideuterionorbornan-7-ol (Ib) (top) and an equimolar mixture of *syn* and *anti* deuterated alcohols (bottom) in carbon tetrachloride containing tetramethylsilane.

(1) The terms *syn* and *anti* will be used to refer to the position of the deuterium atoms with respect to the oxygen function.

solvolysis cannot proceed through the free classical 7-norbornyl cation.

Deuterated *p*-bromobenzenesulfonate (Ia) was prepared from the corresponding alcohol (Ib) by treatment with *p*-bromobenzenesulfonyl chloride in pyridine. The alcohol was prepared by addition of deuterium gas to *anti*-7-norbornenol.<sup>2</sup> The *syn* isomer of alcohol Ib was prepared as an equimolar mixture with the *anti* alcohol by oxidation of *anti* alcohol with chromium trioxide in pyridine followed by lithium aluminum hydride reduction of the resulting ketone. Nuclear magnetic resonance (nmr) spectra are given in Figure 1 for *anti*-2,3-dideuterionorbornan-7-ol (Ib) and for an equimolar mixture of *syn* and *anti* deuterated alcohols.

Deuterated *p*-bromobenzenesulfonate Ia was solvolyzed for 90 min (*ca.* two half-lives) in acetic acid at 205°. The product, 7-norbornyl acetate, was isolated and purified by gas chromatography. Examination of the nmr spectrum of this acetate revealed that it consisted of 90 ± 5% *anti* acetate (Ic) (retention of configuration) and 10 ± 5% *syn* acetate (inversion of configuration).<sup>3</sup> The relative amounts of inversion and retention were unaffected by the presence of added sodium acetate.

Solvolysis of deuterated *p*-bromobenzenesulfonate Ia for 16 hr (*ca.* one half-life) in refluxing formic acid containing sodium formate gave (after saponification of the product formates) deuterated 7-norbornanol with 85 ± 5% retention of configuration.<sup>3</sup>

The predominant retention of configuration in the solvolysis of deuterated *p*-bromobenzenesulfonate Ia may be explained in terms of nonclassical ion II or in terms of classical ion III.

For the case of classical ion III, one assumes that

solvolysis proceeds through front-side collapse of an ion pair. Brown and co-workers have mentioned the possibility of front-side ion-pair collapse.<sup>4,5</sup> Examples of this have been provided by Goering and Chang in the case of 2-phenyl-2-butyl *p*-nitrobenzoate<sup>6</sup> and Shoppee and Johnston in the case of 4,4-dimethylcholestan-3-yl systems.<sup>7</sup>

The classical ion hypothesis is further supported by the fact that on the basis of the acetolysis rate correlations of Foote<sup>8</sup> and Schleyer<sup>9</sup> (a correction has been applied to Foote's correlation<sup>10</sup>) there is no evidence

(2) Alcohol Ib and *p*-bromobenzenesulfonate Ia both contained 88% of the theoretical amount of deuterium. Deuterium analysis was by J. Nemeth, Urbana, Ill.

(3) The analysis was carried out by comparison with the nmr spectra of mixtures of *syn* and *anti* alcohols or acetates of known proportion. Acetates were prepared by acetylation of the alcohols with acetic anhydride in pyridine.

chimeric acceleration in the acetolysis of 7-norbornyl *p*-toluenesulfonate.

Dominant retention of configuration in the solvolysis of deuterated *p*-bromobenzenesulfonate is fully explained by the postulate that nonclassical ion is an intermediate. The corresponding unretained acetate ion was proposed in 1958 by Winstein, *et al.*, in their work on the acetolysis of 7-norbornyl *p*-bromobenzenesulfonate in order to explain the fact that the rearranged acetate formed in this solvolysis, 2-bicyclo[3.2.0]heptyl acetate, is exclusively *trans* isomer.<sup>12</sup> The presence of some *syn*-7-norbornyl product in the present work may be explained by concurrent SN2 reaction (unlikely since sodium acetate does not change the proportion of *anti* acetate in the acetolysis product) or by "leakage" to classical ion III. "Leakage" to a classical ion seems reasonable since there appears to be no rate enhancement in acetolysis.<sup>9-10</sup> There is some rate enhancement, though. (Acceleration by a factor of up to ten or so would not be distinguishable from the scatter in the Foote and Schleyer relations.)

As hoped that the results of the formolysis might be a means of choosing between the classical and nonclassical ion interpretations. If nonclassical ion is involved, formolysis at a lower temperature (100°) would be expected to give relatively more retention than does acetolysis at a higher temperature (205°) on the basis of the fact that in solvolysis *threo*- and *threo*-3-phenyl-2-butyl *p*-toluenesulfonates the amount of retention of configuration increases from 95% to over 99% in going from acetic acid at 75° to formic acid at 25°.<sup>13</sup> On the other hand, if retention is to be explained on the basis of ion pair collapse, formolysis at 100° would be expected to give much more inversion than acetolysis at 205°, on the basis of the fact that Winstein found that acetolysis of *p*-methoxyethyl *p*-toluenesulfonate at 75° needed to be explained in terms of ion pairs and dissociated ions while formolysis at 25° was explained in terms of dissociated ions only.<sup>14</sup> Also, Winstein, *et al.*, report the same finding for 2,4-dimethoxyphenylethyl arenesulfonates.<sup>15</sup> The experimental observations of 10 ± 5% inversion in acetic acid at 205° and 15 ± 5% inversion in formic acid at 100° if anything fit the ion pair explanation slightly better than they do the classical ion explanation, but are clearly about halfway between the extremes cited above. It is

therefore not possible to make a clear-cut choice between the classical and nonclassical ion interpretations at this point.

Further work on the solvolysis of 7-norbornyl *p*-bromobenzenesulfonate is in progress.

## The Structure of Cyclooctatetraeneiron Tricarbonyl in Solution<sup>1</sup>

Sir:

We recently reported that cyclooctatetraeneiron tricarbonyl (COTFe(CO)<sub>3</sub>) in solution has a 1,3-diene-bonded structure (I) and that the nmr spectrum of the compound at -145° is that of the "frozen" structure I.<sup>2</sup> Two other groups of workers, Cotton, Davison, and Faller (CDF)<sup>3</sup> and Keller, Shoulders, and Pettit (KSP),<sup>4</sup> subsequently reached conclusions different from ours. We now show that our original interpretation is correct, and that the deductions of CDF and KSP are invalid.

That COTFe(CO)<sub>3</sub> has structure I in the crystalline state is well established<sup>5</sup> and is not in dispute. CDF<sup>3</sup> present two arguments against COTFe(CO)<sub>3</sub> having structure I in solution, and they suggest a 1,5-diene-bonded (tub) structure under these conditions.

CDF's first argument is that the infrared C-H stretching bands of COTFe(CO)<sub>3</sub> in solution are different from those found in the solid, but are similar to those of 1,5-diene-bonded (tub) COT complexes. However, the great similarity of the fingerprint region of COTFe(CO)<sub>3</sub> in the solid and in solution<sup>6,7</sup> was ignored by CDF. These spectra are presented in Figure 1, together with the spectra of COTMn(CO)<sub>3</sub><sup>7</sup> and COTW(CO)<sub>3</sub>,<sup>8</sup> two compounds which have 1,5-diene-bonded (tub) structures and which display the expected<sup>9</sup> two sharp lines in their nmr spectra ( $\tau$  4.46, 5.80 and 3.66, 5.25, respectively).

In the structurally significant fingerprint region (1600-750 cm<sup>-1</sup>), only very small differences (0.1-0.3%) in the frequencies of COTFe(CO)<sub>3</sub> are observed between the solid and solution spectra. The general

Two of the twenty compounds used by Foote in his correlation are shown to have structures different from those accepted at the time the correlation was published.<sup>11</sup> Also, 7-norbornyl *p*-toluenesulfonate is itself used in establishing the correlation. Consequently, the squares line of the Foote correlation was recalculated omitting compounds whose structures were incorrect (case A) and omitting two compounds and also omitting 7-norbornyl *p*-toluenesulfonate (case B). The results are: case A:  $\log k_{rel} = -0.132$  (1720), correlation coefficient -0.98; case B:  $\log k_{rel} = -0.133$  (1720), correlation coefficient -0.95. The observed rate for 7-norbornyl *p*-toluenesulfonate is  $\log k_{rel} = -7.00$ . The calculated  $\log k_{rel} = -7.00$  (case A) and -7.04 (Case B).

Figure 1.

similarity of the fingerprint region of the spectra of the molybdenum and tungsten (tub) complexes is to be contrasted with the great differences between these spectra on the one hand and the spectra of the iron

complex on the other. Therefore, despite the slight variation in the precise shape of the C-H stretching band<sup>10</sup> of  $COTFe(CO)_3$  in the solid and liquid phases,

the infrared evidence is overwhelmingly in favor of a single structure (1,3-diene bonded) in the two phases.

CDF's second argument is that the chemical shifts found for  $COTFe(CO)_3$  at  $-145^\circ$  are not those expected for structure Ia, especially for the protons on  $C_2$  and  $C_4$ .<sup>11</sup> However, their suggested alternative tub structure certainly does not have the expected chemical shifts,<sup>12</sup> nor does it explain the widths<sup>3</sup> of the bands of the nmr spectrum of  $COTFe(CO)_3$  at  $-145^\circ$ .

KSP<sup>4</sup> accept the 1,3-diene-bonded structure I for  $COTFe(CO)_3$  in solution, but they present the same objections as did CDF<sup>2</sup> to our assignments of chemical

(10) The change in the C-H band of  $COTFe(CO)_3$  on going from solid to solution appears to be due to a broadening of the low-frequency band of the C-H doublet and is not necessarily indicative of a structural change.

(11) On the basis of our published spectrum,<sup>2</sup> we estimate that the highest chemical shift occurring in  $COTFe(CO)_3$  at  $-145^\circ$  is ca.  $\tau$  5.7. Because of the peculiar structure of I, known 1,3-diene-iron tricarbonyl complexes may not be good model compounds. Furthermore, an examination of the literature<sup>3,4,9</sup> indicates that  $H_1$  and  $H_4$  in 1,3-diene complexes have rather variable chemical shifts.

(12) Bonding of metals to olefins results in a high-field shift of the olefinic protons. These shifts<sup>9</sup> are very similar (1.7 and 1.5 ppm, respectively) for norbornadiene and COT upon bonding to  $Mo(CO)_4$ . This should also be true for the corresponding  $Fe(CO)_3$  complexes. For norbornadiene this shift<sup>9</sup> is 3.5 ppm. Therefore the high-field protons in a tub  $COTFe(CO)_3$  complex should be at  $\tau$  4.3 + 3.5 = 7.8, whereas the observed shift is  $\tau \leq 5.7$  ppm.

shifts at  $-145^\circ$ . They agree that the spectrum at  $-145^\circ$  is that of I, but propose that the valency tautomerism  $Ia \rightleftharpoons Ib$  is still very rapid at  $-145^\circ$ . By using plausible chemical shifts (see Ia), they predict that the low-temperature spectrum should consist of two bands at  $\tau$  4.1 and 5.5, roughly as observed.<sup>13</sup>

KSP<sup>4</sup> claim support for their theory from the fact that the nmr spectrum of methylcyclooctatetraeneiron tricarbonyl ( $MeCOTFe(CO)_3$ ) consists of three bands ( $\tau$  4.33, 4.92, and 5.50; intensity ratios of 3:2.3:1.8) at room temperature and of two bands ( $\tau$  4.05 and 5.62, reported as of "approximately equal areas") at  $-120^\circ$ . They argue that the room-temperature band at  $\tau$  5.50 must be the average between two bands, one of which is of the normal olefinic type and at low field; therefore, the other band must be at much higher field than  $\tau$  5.5 for the average to be at  $\tau$  5.5. It is quite clear that this argument is fallacious as is shown below. Thus the nmr spectrum of  $MeCOTFe(CO)_3$  does not support the ideas of KSP.<sup>14</sup>

We now show that the data of KSP on  $MeCOTFe(CO)_3$  are actually in excellent agreement with our interpretation.<sup>2</sup> The evidence indicates that the  $Fe(CO)_3$  group prefers to be attached to certain carbon atoms of the ring of  $MeCOT$ , a possibility ignored by KSP. These carbons are 8123 and 7812 in IIa and IIb, respectively. In our view, the spectrum at low temperatures is that of frozen IIa and IIb, whereas at room temperature the chemical shifts are the average of those in IIa and IIb. On this basis, and using<sup>15</sup> the value  $\tau$  4.1 for any of the protons of noncomplexed olefinic groups and  $\tau$  5.4 for any of the iron-bonded olefinic protons, the chemical shifts shown in Table I

Table I. Predicted Chemical Shifts for IIa and IIb

Positions	Chemical shifts at $-145^\circ$ , $\tau$		Av of IIa and IIb (intensity) at room temp
	IIa	IIb	
2 and 8	5.4, 5.4	5.4, 5.4	5.4 (2)
3 and 7	5.4, 4.1	4.1, 5.4	4.75 (2)
4 and 6	4.1, 4.1	4.1, 4.1	4.1 } (3)
5	4.1	4.1	4.1 }

are predicted for  $MeCOTFe(CO)_3$  at  $-145^\circ$  and at room temperature. The predicted low-temperature spectrum ( $\tau$  4.1 and 5.4, relative intensities 4:3) and the high-temperature spectrum ( $\tau$  4.1, 4.75, and 5.4, relative intensities 3:2:2) are in substantial agreement with those reported by KSP.<sup>4</sup> Valency tautomers with the  $Fe(CO)_3$  at positions different from those in IIa or IIb give calculated spectra in gross disagreement with the experimental data and thus cannot be present in significant amounts.

(13) The high-field band<sup>2</sup> of  $COTFe(CO)_3$  is actually much too broad and complex to be due to four protons all having the same chemical shift, as is required by KSP's theory.

(14) These authors do not attempt to explain the spectra of  $MeCOTFe(CO)_3$ . We find that it is impossible to explain both the room- and low-temperature spectra of  $MeCOTFe(CO)_3$  with KSP's theory.

(15) For this calculation we have used rounded values of the chemical shifts given by KSP.<sup>4</sup>

The spectra of a deuterated derivative of  $MeCOTFe(CO)_3$ , described in the accompanying communication,<sup>16</sup> confirm our conclusions.

## Valency Tautomerism in Methylcyclooctatetraeneiron Tricarbonyl<sup>1</sup>

Sir:

We have shown<sup>2</sup> that the nmr data of Keller, Shoulders, and Pettit on methylcyclooctatetraeneiron tricarbonyl (I) can best be explained on the basis that the  $Fe(CO)_3$  group exhibits a preference for bonding with carbon atoms 1, 2, 7, and 8 (Ia) or 1, 2, 3, and 8 (Ib) of the ligand, and that valency tautomerism,  $Ia \rightleftharpoons Ib$ , is fast (on the nmr time scale) at room temperature, but slow at  $-145^\circ$ . An examination of the nmr spectrum of methyl-*d*-cyclooctatetraene-2,3,4,5,6,7-*d*<sub>6</sub>-iron tricarbonyl (II), presented in this communication, confirms our deductions and clearly shows that the terminal and internal protons in the iron-bonded diene moiety of II have only slightly different chemical shifts.

Lithium aluminum hydride reduction of cyclooctatetraenyl-2,3,4,5,6,7-*d*<sub>6</sub>-methyl-*d* bromide<sup>3</sup> in diethyl ether gave methyl-*d*-cyclooctatetraene-2,3,4,5,6,7-*d*<sub>6</sub> (III)<sup>4</sup> as a yellow oil, isolated by glpc. Reaction of III with an equimolecular amount of  $Fe_2(CO)_9$  in boiling hexane for a few minutes gave, after removal of the solvent, the dark red complex<sup>5</sup> II, which was purified by evaporative distillation *in vacuo*.

The nmr spectrum of II in deuterated chloroform showed only two bands: the  $CH_2D$  protons at  $\tau$  8.15 and the ring proton at  $\tau$  5.44. The high-field chemical shift of the ring proton is only consistent with IIa and IIb being the dominant species at room temperature.<sup>6</sup>

In  $CHCl_2F$  solution, the ring proton in II changed from a sharp line at room temperature to two sharp lines at  $-145^\circ$  (Figure 1). No change was observed in the  $CH_2D$  band, apart from some broadening at very low temperatures.<sup>7</sup> At the coalescence temper-

(2) F. A. L. Anet, H. D. Kaesz, A. Maasbol, and S. Winstein, *J. Am. Chem. Soc.*, **89**, 2489 (1967).

(3) F. A. L. Anet, A. J. R. Bourn, and Y. S. Lin, unpublished results; cf. F. A. L. Anet, A. J. R. Bourn, and Y. S. Lin, *J. Am. Chem. Soc.*, **86**, 3576 (1964). The undeuterated compounds have been prepared previously: A. C. Cope and H. C. Campbell, *ibid.*, **74**, 179 (1952); A. C. Cope, R. M. Pike and D. F. Rugen, *ibid.*, **76**, 4945 (1954).

(4) The rate of bond shift in III has been determined from the temperature dependence of the nmr spectrum, which also confirms the structure and isotopic labeling of the compound (to be published).

(5) The same procedure applied to cyclooctatetraene was found to give a good yield of pure iron tricarbonyl complex. Mass spectra of II showed a ratio of I-*d*:I-*d*<sub>6</sub>:I-*d*<sub>8</sub> of 30:5:1 and a cracking pattern consistent with its structure.

(6) Other tautomers would have the ring proton at least half of the time in the unbonded diene portion of the molecule and would therefore exhibit a low chemical shift ( $\tau < 5$ ). The presence of appreciable amounts of these tautomers would lower the average chemical shift of the ring proton of II, as compared with the high-field band (ca.  $\tau$  5.5) in the spectrum of  $COTFe(CO)_3$  at  $-145^\circ$ .

(7) The greater broadening of the  $CH_2D$  protons relative to the ring proton is consistent with the closeness of the two protons in the  $CH_2D$

Figure 1. Proton spectrum (60 Mc/sec, deuterons decoupled) of II in  $\text{CHCl}_2\text{F}$  at various temperatures. Only the olefinic region is shown. The scale is cps downfield from internal tetramethylsilane.

ature ( $-125^\circ$ ) for the ring-proton bands, the rate constant for the valency tautomerism,  $\text{IIa} \rightleftharpoons \text{IIb}$ , is  $35 \text{ sec}^{-1}$ , and the free energy of activation ( $\Delta F^\ddagger$ ) is  $7.5 \text{ kcal/mole}$ , a value close to the  $7.2 \text{ kcal/mole}$  observed<sup>8</sup> for the parent compound.

The average of the chemical shifts of the two ring-proton bands at  $-150^\circ$  is very close to the chemical shift of the coalesced bands (e.g., at  $-100^\circ$  or higher). This is in agreement with the conclusion based on the chemical shift of the ring proton that tautomers other than IIa or IIb must be present in very small amounts.

Tautomers other than IIa or IIb should show a ring-proton band at low field (ca.  $\tau$  4) at  $-145^\circ$ , but unfortunately this region is partly obscured by a  $^{13}\text{C}$  satellite of the solvent as well as being very close to an group and relaxation by the direct spin-spin interactions modulated by molecular rotation.

(8) C. G. Kreiter, A. Maasbol, F. A. L. Anet, H. D. Kaesz, and S. Winstein, *J. Am. Chem. Soc.*, **88**, 3444 (1966).

intense solvent peak. We plan to examine the spectrum further in a deuterated solvent, which should allow the detection of small peaks in this region. On the basis of the present evidence, it appears that more than 90% of II is in the form of IIa and IIb.

The present work does not allow an unambiguous assignment to be made to the ring-proton bands in the low-temperature spectrum of II. Since the ring proton in IIb would be expected to be upfield from that in IIa,<sup>9</sup> the bands at  $\tau$  5.42 and 5.68 can be assigned tentatively to IIa and IIb, respectively.

The origin of the low energy of IIa and IIb is of interest. In IIa or IIb the methyl group is attached to a ring carbon atom which in cyclooctatetraeneiron tricarbonyl<sup>10</sup> has an internal angle of  $124.6^\circ$ . In other tautomers of II the methyl group would be attached to carbon atoms having internal angles greater than  $130^\circ$ . From previous work<sup>3,11</sup> on the rates of ring inversion and bond shift in derivatives of cyclooctatetraene (COT), it is known that large groups, and even methyl groups,<sup>12</sup> destabilize the planar form of COT (bond angles of  $135^\circ$ ) relative to the tub form (bond angles of about  $125^\circ$ ). This effect was ascribed to the greater steric repulsions existing between a substituent and adjacent hydrogen atoms in the planar form relative to the tub form. Although II is nonplanar, these steric effects should operate to make IIa and IIb more stable than other tautomers. Steric repulsions between the  $\text{Fe}(\text{CO})_3$  and the methyl group would destabilize IIa and IIb and therefore do not appear to be important. Inductive and hyperconjugative effects of the methyl group may be significant in stabilizing IIa and IIb; experimental investigations of this possibility are planned.

(12) The rate constant for bond shift<sup>4</sup> in III at  $-10^\circ$  is not more than one-tenth of that<sup>11</sup> in cyclooctatetraene.

## Mass Spectrometric Evidence for the Gaseous $\text{Si}_2\text{N}$ Molecule

Sir:

Optical spectroscopic studies<sup>1</sup> and ionic-model calculations<sup>2</sup> have indicated that the binding energies of gaseous nitrides should be of the order of  $100 \text{ kcal mole}^{-1}$ , and thus one expects that gaseous nitrides should be relatively stable. Most of the refractory nitrides have been reported, however, to dissociate when heated under vacuum.<sup>3-7</sup> Only gaseous gallium

has been observed mass spectrometrically,<sup>8</sup> attempt was made to establish its stability. Spectra have been cited as evidence for gaseous and TiN.<sup>10</sup>

In the course of a mass spectrometric study of the atomization of silicon from a boron nitride Knudsen cell the  $\text{Si}_2\text{N}$  molecule has been identified in the gas.

This species is isoelectronic with the well-established gaseous species  $\text{C}_2\text{N}$  for which both the CCN and NC isomers are known from optical spectra.<sup>11</sup>

Experiments were performed on a 12-in. radius, cylindrical mass spectrometer, similar to that described by Chupka and Inghram.<sup>12</sup> The Knudsen cell was made from a high-purity boron nitride rod and was fitted into a heavy tantalum crucible. The cell was heated by electron bombardment, and the temperature was measured with an optical pyrometer fitted into the blackbody hole in the bottom of a tantalum crucible.

When the cell heated above 1500°K, the main peaks in the mass spectrum were  $\text{N}_2^+$  and  $\text{Si}^+$ , both increasing with temperature. At temperatures above 1700°K, the peaks for  $\text{Si}_2^+$ ,  $\text{Si}_3^+$ , and  $\text{Si}_4^+$ , as well as peaks at  $m/e$  70, 71, and 72, were observed. From the isotopic abundance ratios the peaks at masses 70, 71, and 72 were identified with the  $\text{Si}_2\text{N}^+$  ion. The appearance potential, determined by the vanishing-current method, for the ionization potential of Si as standard was 0.3 eV. This value suggests that the  $\text{Si}_2\text{N}^+$  ion is formed by direct ionization of the  $\text{Si}_2\text{N}$  molecule and fragmentation.

It was impossible in these experiments to decide unambiguously whether the molecules  $\text{Si}_2\text{N}_2$  or  $\text{Si}_2\text{N}_4$  were present in the vapors, because of interference of  $\text{Si}_3^+$  and  $\text{Si}_4^+$  ions at the same mass.

Ion intensities of  $\text{Si}^+$ ,  $\text{N}_2^+$ , and  $\text{Si}_2\text{N}^+$  were recorded at several temperatures in the range 1742–1760°K and were used to calculate the equilibrium constant for the reaction

using the JANAF<sup>13</sup> free-energy functions for  $\text{Si(g)}$  and  $\text{N}_2\text{(g)}$ , values for  $\text{Si}_2\text{N(g)}$ , estimated by analogy with

#### Sulfur Dioxide Insertion. IV. A New Allylic Rearrangement<sup>1</sup>

Sir:

The unusual paucity of data on insertion reactions of  $\sigma$ -bonded allylic complexes of the transition elements<sup>2</sup> prompted us to examine the behavior of several such organometallics toward sulfur dioxide. Reported now are some preliminary results on a new type of rearrangement which accompanies insertion of  $\text{SO}_2$  into metal-carbon bonds.

The qualitative observation of one of us (F. A. H.) that allylmanganese pentacarbonyl inserts sulfur dioxide at a rate much faster than do the methyl and benzyl analogs<sup>3</sup> suggested a possibility of mechanistic differences between these reactions. Particularly inviting was a path involving an allylic rearrangement resulting from cleavage of the Mn-C(1) bond and formation of the Mn-S and S-C(3) bonds (eq 1). In order to test for this possibility we have examined the reaction of

sulfur dioxide with 2-butenylmanganese pentacarbonyl and with 3-methyl-2-butenylmanganese pentacarbonyl, since structures of the sulfinato products of these reactions should resolve readily the question of occurrence of the postulated rearrangement.

**Figure 1.** Proton magnetic resonance spectra of sulfinatopentacarbonylmanganese(I) complexes obtained from the reaction of sulfur dioxide with (A) 2-propenylpentacarbonylmanganese, (B) 2-butenylpentacarbonylmanganese, (C) 3-methyl-2-butenylpentacarbonylmanganese (recorded on a Varian Associates A-60 spectrometer in  $\text{CDCl}_3$  solution).

In a typical reaction, an allylmanganese pentacarbonyl complex<sup>4</sup> (ca. 3 g) was allowed to interact with about 15 ml of anhydrous liquid sulfur dioxide at ca.  $-40^\circ$  for approximately 2 hr.<sup>5</sup> The  $\text{SO}_2$  was then re-

(4) Prepared from sodium pentacarbonylmanganate(-1) and the organic halide; see W. R. McClellan, H. H. Hoehn, H. N. Cripps, E. L. Muetterties, and B. W. Howk, *J. Am. Chem. Soc.*, **83**, 1601 (1961). The compound was characterized by nmr spectroscopy.

(5) Actually, these reactions reach completion in much shorter times.

moved, the orange residue was extracted with 20 ml of absolute ethanol, and 10 ml of ether was added to the extracts. Cooling the resulting solution to  $-40^\circ$  for 1 hr caused separation of pale yellow crystals. The product was washed with 20 ml of ether and then recrystallized from chloroform-hexane. The yield ranged from 70 to 80%.

The infrared carbonyl and sulfur–oxygen stretching frequencies of the products, listed in Table I, are very similar to those reported for the analogous methyl,<sup>3</sup> ethyl,<sup>6</sup> and benzyl<sup>3</sup> derivatives and attest to the S-sulfinatopentacarbonyl formulation of the complexes. Supplementary data are given in Table II.

The question concerning the position of attachment of the allyl moieties to sulfur in  $(\text{CO})_5\text{MnSO}_2\text{C}_4\text{H}_9$  and  $(\text{CO})_5\text{MnSO}_2\text{C}_6\text{H}_5$  is resolved upon examination of the proton magnetic resonance spectra of these derivatives in conjunction with the spectrum of the 2-propenylpentacarbonyl sulfinato, all shown in Figure 1. The nmr spectrum of  $(\text{CO})_5\text{MnSO}_2\text{C}_3\text{H}_5$  consists of a doublet centered at  $\tau$  6.25 and of a complex multi-line absorption farther downfield (relative intensities 2:3). The former signal is assigned to the two protons of the methylene group bonded to  $\text{SO}_2$ , and the latter to the three vinyl hydrogens. The salient features in the spectrum of  $(\text{CO})_5\text{MnSO}_2\text{C}_4\text{H}_9$  are presence of a multiplet at  $\tau$  6.10–6.38 and of a complex absorption pattern at  $\tau$  3.59–4.66 (relative intensities 1:3). No signal is detectable in the  $\tau$  5–7 range of the spectrum of  $(\text{CO})_5\text{MnSO}_2\text{C}_6\text{H}_5$ ; the resonances at  $\tau$  3.91–4.83 and the sharp line at  $\tau$  8.59 (due to the six methyl protons) occur with the intensity ratio of 3:6.

These data are in complete agreement with the structures containing rearranged allylic moieties of the last two derivatives (see Figure 1). Had there been no rearrangement, each spectrum would be expected to ex-

(6) F. A. Hartman, Ph.D. Thesis, The Ohio State University, 1966.

a doublet at  $\tau$  5–7 with the relative intensity corresponding to two methylene protons. Furthermore downfield signals would occur with the relative intensities and multiplicities reflecting the presence of and one vinyl protons in the  $C_4H_7$  and  $C_5H_9$  sulfates, respectively.<sup>7</sup>

The generality of the above-described allylic rearrangement is supported by the behavior of the 2-butenyl derivatives of cyclopentadienyliron dicarbonyl, cyclooctadienylmolybdenum tricarbonyl, and cyclopentadienyltungsten tricarbonyl toward sulfur dioxide. The spectra of all of the resulting sulfinates are consistent with the rearranged structure of the hydrocarbon moiety.<sup>9</sup>

We are currently examining insertion reactions between allyl metal complexes and substrates other than sulfur dioxide with a view to elucidating the scope of the rearrangement described herein.

**Acknowledgment.** The support of the National Science Foundation and of the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged.

This argument receives support from the recent isolation of  $\alpha(CO)_2SO_2CH_2CH=C(CH_3)_2$  via the reaction of  $Na[C_5H_5Fe(CO)_2]$  with sulfur dioxide with 1-chloro-3-methyl-2-butene. The protonic resonance spectrum of the sulfinate exhibits doublets at  $\tau$  6.17 ( $CH_2$ ) and 6.17 ( $CH_2$ ) with the relative intensity ratio of 6:2, a singlet at  $\tau$  4.68 ( $C_5H_5$ ), and a complex signal at  $\tau$  4.30–4.95 ( $C$ ), in complete accord with the proposed allylic attachment.<sup>8</sup>

R. L. Downs and A. Wojcicki, to be published. Although we cannot rule out the possibility that the "rearranged" sulfinato complexes result from the initial formation of the corresponding "normal" allyl sulfinates, which then rapidly undergo isomerization, there is evidence against such a sequence of events. The five  $C_5H_5Fe(CO)_2SO_2CH_2CH=C(CH_3)_2$  retains its identity after refluxing in liquid  $SO_2$ ; a 3:1 mixture of the geometric isomers  $\alpha(CO)_2SO_2CH_2CH=C(CH_3)_2$  and  $C_5H_5Fe(CO)_2SO_2C(CH_3)_2CH=C(CH_3)_2$  comes ca. 8:1 and 14:1 upon refluxing for 4 and 8 hr, respectively, with sulfur dioxide. Thus, at least in this case, isomerization of the isomers does occur, albeit of the sterically more hindered  $C_5H_5Fe(CO)_2C(CH_3)_2CH=C(CH_3)_2$  to the less crowded  $C_5H_5Fe(CO)_2SO_2CH_2CH=C(CH_3)_2$ .

## c Polyethers and Their Complexes Metal Salts

Forty-three cyclic polyethers, derived from aromatic diols and containing from 9 to 60 atoms in the ring, have been synthesized. Some of these have been prepared in good yield without the use of a high-dilution technique. Many of the compounds have been catalytically hydrogenated to the corresponding saturated cyclic polyethers.

Many of these cyclic polyethers have the unusual ability of forming relatively stable complexes with alkali and alkaline earth metal ions. The more effective ligands are those containing 5–10 oxygen atoms, separated from the next by 2 carbon atoms. This communication deals primarily with two examples of  $\alpha$ -oxygen compounds which are the most effective versatile complexing agents: an aromatic compound derived from catechol, 2,3,11,12-dibenzo-1,13,16-hexaoxacyclooctadeca-2,11-diene (I); and

Figure 1.  $\alpha$ -Benzo or 1,2-cyclohexyl polyethers.

its hydrogenation product, a mixture of *cis-trans* isomers, 2,5,8,15,18,21-hexaoxatricyclo[20.4.0.0<sup>9,14</sup>]-hexacosane (II).

The two cyclic polyethers form stable complexes with ionic compounds of Li, Na,  $NH_4$ ,  $RNH_3$ , K, Rb, Cs, Ag(I), Ca, Sr, Ba, Cd, Hg(I), Hg(II), La(III), Tl(I), Ce(III), and Pb(II). The complexes are thought to be field valency compounds formed by ion-dipole interaction between the cation and the negative dipoles of the oxygen atoms of the polyether ring, as shown in Figure 1; the formation of stable ammonium complexes supports this interpretation. The "hole" in I and II, estimated to be 4 Å in diameter, is large enough to accommodate any unsolvated or uncoordinated inorganic cation. The stoichiometry of the complexes is one molecule of polyether per single cation regardless of the valence.

Compound I is prepared by treating 1 mole of catechol, 2 moles of sodium hydroxide, and 1 mole of bis(2-chloroethyl) ether in 1-butanol at reflux temperature (115°) for about 24 hr. The yield is 44–48%, and 1 mole (360 g) of product can be synthesized in a volume of 5 l. White fibrous crystals are obtained by crystallization from benzene; mp 164°; bp ca. 380–384° (769 mm). *Anal.* Calcd for  $C_{20}H_{24}O_8$ : C, 66.6; H, 6.7; mol wt, 360. Found: C, 66.3; H, 6.8; mol wt, 371. Compound I is readily soluble in methylene chloride and chloroform, and very little soluble in methanol and water. Its ultraviolet spectrum in methanol has a peak at 274 m $\mu$  ( $\epsilon$  5200). Its infrared spectrum shows no OH band but two strong, broad ether bands near 8.1 and 8.5  $\mu$ . Its nmr spectrum is consistent with the proposed structure: a multiplet 4.11 ppm downfield from TMS, area ratio 2.2, and a singlet, 6.92 ppm, area ratio 1.00. The good yield of I obtained without resorting to a high-dilution technique is unusual for an 18-membered ring. Possibly the sodium ions promote ring formation by properly orienting the reactants and the intermediate products through ion-dipole interaction.

Compound II is prepared by hydrogenating I in a stainless steel autoclave at 100° and 1600 psig using *p*-dioxane as solvent and ruthenium dioxide as catalyst. The product, free of alcoholic by-products, is obtained by chromatography with acid-washed alumina and *n*-heptane in 67% yield. *Anal.* Calcd for  $C_{20}H_{36}O_8$ : C, 64.5; H, 9.7; mol wt, 372. Found: C, 64.5; H, 9.6; mol wt, 378. The product is a mixture of isomers, melts between 30 and 56°, and boils at about 344° (769 mm). It is soluble in organic solvents including petroleum ether. Its solubility in water at 26° is 0.036 mole/l. and decreases with rising temperature. Its ultraviolet spectrum shows no significant absorption above 200  $\mu$ , and its infrared spectrum shows no OH band but a strong, broad ether band near 9  $\mu$ . Its nmr spectrum is consistent with the proposed structure: a multiplet 1.50 ppm downfield from TMS,

area ratio 1.17, and a singlet, 3.67 ppm, area ratio 1.00.

Crystalline 1:1 complexes of I have been prepared with, for example,  $\text{LiI}_3$ ,  $\text{NaNO}_3$ ,  $\text{KI}$ ,  $\text{KCNS}$ ,  $\text{NH}_4\text{CNS}$ ,  $\text{CN}_3\text{NH}_2\text{CNS}$ ,  $\text{RbCNS}$ ,  $\text{CsCNS}$ ,  $\text{CaCl}_2$ ,  $\text{Ba}(\text{OH})_2$ ,  $\text{CdCl}_2$ ,  $\text{HgCl}_2$ , and  $\text{Pb}(\text{OAc})_2$ . The potassium thiocyanate complex can be obtained as long, glistening crystals melting at  $248\text{--}249^\circ$ , considerably higher than the melting points of the components ( $172^\circ$  for potassium thiocyanate). The ammonium thiocyanate complex melts at  $187\text{--}189^\circ$  ( $149^\circ$  for ammonium thiocyanate). The analytical data on the complexes are satisfactory.<sup>1</sup>

The solubility of I in polar solvents is increased by the addition of soluble complexable salts. For example, the solubility of I in methanol at  $30^\circ$  (1.1 mmoles/l.) is increased to the following values by the presence of the salts at 25 mM:  $\text{NaCNS}$ , 23.6 mmoles/l.,  $\text{KF}$ , 24.7;  $\text{RbCNS}$ , 25.6;  $\text{AgNO}_3$ , 22.2;  $\text{SrCl}_2$ , 17.9; and  $\text{BaCl}_2$ , 26.6. The complexes tend to be more soluble in organic solvents of high dielectric constant, but most are decomposed by water. All soluble, ionic compounds of the complexable elements form complexes in solvents, such as methanol, regardless of the anion.

Compound II, being a mixture of isomers, forms solid complexes with not so well-defined melting points, but always higher than the melting point of II itself. Some of its complexes, such as that of potassium triiodide, are stable to water. II has the useful property of solubilizing ionic compounds in aprotic solvents including aromatic hydrocarbons. The following are a few examples. Crystals of potassium permanganate are insoluble in benzene, but they begin to dissolve immediately after the addition of II and continue to dissolve until the concentration of permanganate exceeds 0.02 M. Crystals of palladium chloride are insoluble in *o*-dichlorobenzene, but when crystals of potassium chloride and II are added, they go into solution as the complex of II with  $\text{K}_2\text{PdCl}_4$ . The salts of many other alkali, alkaline earth, and transition metals have been solubilized by these two methods. A most interesting and useful complex is that of II with potassium hydroxide, which is soluble in toluene to over 0.3 mole/l. This solution saponifies the hindered esters of 2,4,6-trimethylbenzoic acid by the normal acyl-oxygen fission.

Not all complexable salts, however, can be solubilized even in the better aprotic solvents. Salts of high crystal lattice energy, such as potassium fluoride, sulfate, nitrate, phosphate, and carbonate, do not form complexes in aprotic solvents, and neither can these complexes be isolated as solids from protic solvents, such as methanol.

A detailed paper on the cyclic polyethers and their complexes with metal salts is being prepared for publication.

(1) Crystalline etherates of the alkali metal salts have not been common heretofore. Two  $[(\text{Na}(\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_2)_4)]_2[\text{Ta}(\text{CO})_6]$  and  $[\text{K}(\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_2)_4][\text{Mo}(\text{CO})_6]$  are mentioned by F. A. Cotton and G. Wilkinson, "Advanced Inorganic Chemistry," Interscience Publishers, Inc., New York, N. Y., 1962, p 318.

## Observation of Helix-Coil Transition Using Nuclear Magnetic Resonance Halogen Ion Probe Technique

Sir:

Recent work has shown that nuclear magnetic resonance of halide ions may be a valuable tool for investigating the gross physical characteristics and specific chemical reactivities of large biological molecules in solution.<sup>1</sup> This note reports an observation of the well-substantiated helix-coil transition in synthetic poly-L-glutamate using  $^{35}\text{Cl}$  resonance, and thus illustrates a direct application of wide-line nmr to the study of macromolecular structure. The  $^{35}\text{Cl}$  line width is usually determined by quadrupole relaxation so that in the extreme narrowing limit the line width for a nucleus of spin  $3/2$  is given by eq 1, where  $\Delta\nu$  is the

$$\Delta\nu = \frac{2\pi}{5} (e^2qQ)^2\tau_c \quad (1)$$

full line width in cycles per second at half-height,  $q$  is the electric field gradient at the nucleus with quadrupole moment  $Q$ ,  $\tau_c$  is the correlation time for molecular rotation, and the asymmetry parameter has been neglected.<sup>2</sup> In aqueous sodium chloride solutions the chloride ion is symmetrically solvated producing a field gradient at the nucleus close to zero and a line width of about 16 cps. If, however, the quadrupolar chlorine nucleus can be found at environmentally different sites in solution, the line width will depend on the relative concentration of each site, the values of  $(e^2qQ)^2$  and  $\tau_c$  associated with each site, as well as the frequency with which the  $^{35}\text{Cl}$  nucleus samples the various sites. In the case where exchange of the chloride is fast with respect to  $1/\pi\Delta\nu$ , a single composite line is observed with the line width given by

$$\Delta\nu = (\Delta\nu_a)P_a + (\Delta\nu_b)P_b \quad (2)$$

where  $\Delta\nu_a$  and  $\Delta\nu_b$  are the contributions to the line width associated with sites a and b, while  $P_a$  and  $P_b$  are the probabilities that the chlorine is at site a and b, respectively.<sup>3</sup>

When a 2 M sodium chloride solution is made  $10^{-3}$  M in mercuric chloride, the  $^{35}\text{Cl}^-$  resonance is broadened to 34 cps. The effect is explained by the rapid exchange of chloride ions in solution with the covalent chlorine associated with the  $\text{HgCl}_4^{2-}$  complex; thus, eq 2 correctly describes the line width. Since a similar effect is observed with species of the type  $\text{RSHgCl}$  in sodium chloride solutions, where R is almost any organic molecule, the mercury atom provides a convenient label for investigating changes in the correlation time of the molecule to which it is attached.<sup>1</sup>

In aqueous solutions of low pH, poly-L-glutamate acquires a helical structure while at higher pH the randomly coiled form predominates. The transition from the helical to the randomly coiled structure has been investigated as a function of pH using measurements of optical rotation, viscosity, per cent ionization, optical rotatory dispersion, and the infrared spectrum.<sup>4,5</sup> In solutions of low salt concentration the

(2) A. Abragam, "The Principles of Nuclear Magnetism," The Clarendon Press, Oxford, 1961, p 314.

(3) T. J. Swift and R. E. Connick, *J. Chem. Phys.*, **37**, 307 (1962).

sition is quite sharp at about pH 5.8, but in 0.2 M sodium chloride the transition is shifted to approximately pH 5.2.

poly-L-glutamic acid (DP 530) as the sodium salt was hased from Pilot Chemical Co. Sodium chloride, mercuric chloride, sodium hydroxide, and potassium hydrogen phthalate were purchased as analyzed reagents from the Baker Chemical Co. The N-acetyl-DL-homocysteine thiolactone was obtained from Professor L. Stryer of Stanford University. The  $^{55}\text{Cl}$  width measurements were made on a Varian A-60 nmr spectrometer at 4.3 Mc using 500-Hz modulation and lock-in-detection to stabilize the line.

poly-L-glutamate was labeled at the terminal amide function by reaction with N-acetyl-DL-homocysteine thiolactone using the method reported by Benesch and Scheraga.<sup>6</sup> The solutions measured were made using a 0.1 M hydroxide-potassium hydrogen phthalate buffer at a pH range from 4 to 8. All solutions were 1.0 M in sodium chloride,  $1.0 \times 10^{-4}$  M in mercuric chloride, and 0.18% poly-L-glutamate by weight. On mixture labeled poly-L-glutamate with the mercury solution the mercury adds to the -SH group so that the molecule observed may be represented as

though the mercury(II) is in approximately a tenfold excess, the line broadening caused by  $10^{-4}$  M mercury in 1.0 M sodium chloride is less than 2 cps.<sup>7</sup> Under these conditions the probabilities of the chloride being at each site are a constant from one solution to the next so that any change in line width reflects only changes in the correlation time of the mercury site caused by the variations of pH. The experimental results are summarized in Figure 1.

The detailed features of the experimental curve are in excellent agreement with those reported by Idelson and Doty for optical rotation as a function of pH for a 0.2% solution of poly-L-glutamate in 0.2 M sodium chloride.<sup>4</sup> That plot, however, there was a maximum at about 4.6 and the authors suggested that the decrease in the maximum rotation associated with the helical transition could be caused by a contraction of the helix resulting from protonation of the carboxyl groups. In the case of such a maximum is consistent with the data in Figure 1, the data are also consistent with a straight line of zero slope. This indicates that a change in the correlation time for the helix associated with such a transition is on the order of the experimental error of this technique. These results demonstrate that the mercury ion probe is a sensitive technique for the investigation of structural properties and gross behavior of large molecules in solution.

## Oxidation of Radon in Aqueous Solutions

Sir:

We have observed an apparent oxidation of radon in aqueous oxidizing solutions under certain conditions. Previously, Fields, Stein, and Zirin reported that a radon fluoride of low volatility was formed when radon and fluorine were heated to  $400^\circ$ ,<sup>1</sup> but research on the chemistry of radon has been limited because of the short half-life and high specific activity of radon, a radioactive daughter of radium.

In our experiments,  $10^{-7}$  M  $\text{RaBr}_2$  solutions were allowed to remain in contact with various aqueous, oxidizing solutions for a period of 23 days or longer (six half-lives of radon). These solutions were then extracted with equal amounts of hexane. The relative amounts of radon in the two phases were determined by counting the 0.35-Mev  $\alpha$  activity of a subsequent daughter,  $^{214}\text{Pb}$ . The samples were counted after a 2-hr aging period which was sufficient time to essentially establish a state of secular equilibrium between the  $^{222}\text{Rn}$  and the  $^{214}\text{Pb}$ . The ratios of the  $^{214}\text{Pb}$  counting rates in the two phases are given in Table I as the distribution ratio of radon between hexane and the various aqueous solutions. The error given is the standard deviation of the 6-12 trials run on each particular aqueous phase. A change from a nonpolar species in water to a polar or ionic species in oxidizing solutions is apparent. This behavior is not due to merely the influence of electrolyte in the aqueous phase. Tatsuya

Figure 1. Anion exchange of nonoxidized Rn (●) in  $\text{H}_2\text{O}$  and oxidized Rn (○) in  $0.1 \text{ M K}_2\text{S}_2\text{O}_8$ , made strongly alkaline with  $\text{NH}_4\text{OH}$ .

and Yamasaki<sup>2</sup> have shown that addition of strong electrolyte to water lowers the solubility of radon in that phase, whereas in our experiments, the opposite effect was observed in that the distribution ratio for extraction was diminished when oxidizing electrolytes were present in the aqueous phase.

Table I. Distribution Ratios for Extraction of Radon into Hexane from Aqueous Solution

Aqueous phase (all contained $\text{RaBr}_2$ )	Distribution ratios (hexane/aqueous)
$\text{H}_2\text{O}$	$33.2 \pm 6.3$
5% $\text{H}_2\text{O}_2$	$10.4 \pm 1.5$
5% $\text{H}_2\text{O}_2$ -1 N $\text{HNO}_3$	$7.0 \pm 0.9$
25% $\text{H}_2\text{O}_2$	$4.3 \pm 1.8$
25% $\text{H}_2\text{O}_2$ -1 N $\text{HNO}_3$	$3.4 \pm 1.5$
0.5 M $\text{K}_2\text{Cr}_2\text{O}_7$	$7.3 \pm 0.8$
0.2 M $\text{KMnO}_4$	$2.6 \pm 0.8$
0.1 M $\text{K}_2\text{S}_2\text{O}_8$	$0.2 \pm 0.1$

This apparent oxidation of radon is substantiated by the results of flushing the aqueous solutions with air or argon. Five times the amount of radon was removed from a nonoxidizing solution as was removed

(2) S. Tatsuya and A. Yamasaki, *Bull. Chem. Soc. Japan*, **38**, 1110 (1965).

from an oxidizing solution after 1 hr of bubbling air through the solutions. Further argon flushing of the nonoxidizing solution removed an additional small amount of radon, while further flushing of the oxidizing solution produced no additional loss.

Ion-exchange experiments were conducted with the radon from the  $0.1 \text{ M K}_2\text{S}_2\text{O}_8$  and the 25%  $\text{H}_2\text{O}_2$  solutions. They have shown the oxidized radon species to be nonionic in a neutral or acidic solution and to be negatively charged in a strongly alkaline solution. The resins used were 100–200 mesh Dowex 1-X8 anion exchanger ( $\text{Cl}^-$  form) and Dowex 50-X8 cation-exchange resin ( $\text{H}^+$  form). The anion-exchange resin bed was washed exhaustively with sodium hydroxide to convert the resin to the hydroxide form. The various radon solutions were allowed to flow through the particular resin at a rate of 1 ml/min. The elution process then consisted simply of passing the desired eluent through the column at the same rate and collecting the eluate in 5-ml fractions. The amount of radon in each fraction was then determined in the previously described manner. The eluents consisted of water,  $0.1 \text{ M NaCl}$ , and  $0.1 \text{ M Cr}(\text{NO}_3)_3$ , consecutively. Oxidized radon in solutions that had been made strongly alkaline with ammonium hydroxide (trials at pH 11.4, 11.8, and 12.5) was retained on the anion-exchange column. Elution was not accomplished with water or chloride ions, but the radon was removed by elution with nitrate ions (see Figure 1). Oxidized radon in a neutral or acidic solution, when passed through the anion-exchange column, could be eluted with water. The same was found for oxidized radon, regardless of acidic or basic conditions, when passed through the cation-exchange resin. Nonoxidized radon produced from radium decay in water was not retained on either the cation- or anion-exchange resin regardless of the pH of the radon solution. Figure 1 gives an example of nonoxidized radon passed through an anion-exchange resin.

Oxidized radon in neutral or acidic solutions behaved as a polar but nonionic species. It was non-extractable into hexane, and, when it was passed through either an anion- or cation-exchange column, a larger volume of water (ca. 25 ml) was required for elution than was required for the elution of the nonoxidized form (ca. 5 ml).

If an analogy is drawn between radon and xenon,<sup>3,4</sup> the oxidized radon species could be  $\text{RnO}_2$  below a pH of 11 and  $\text{HRnO}_4^-$  above a pH of 11. However, further work is required to reveal the extent to which any such analogy can be made.

The oxidation of radon has been accomplished only in solutions in which  $^{222}\text{Rn}$  has been allowed to come to secular equilibrium with  $^{226}\text{Ra}$ . Attempts at oxidizing elemental radon, which had previously been separated from its parent radium, have been unsuccessful.<sup>5</sup>

## Formation of Small Peptides. I.

### Secondary Structure in a Tetrapeptide

Previous work in this laboratory has shown that a folded hexapeptide is hydrogen-bonded intramolecularly between the two tripeptide moieties.<sup>1</sup> Goodman earlier reported that the onset of secondary structure occurred at the pentapeptide level in small peptides.<sup>2</sup> It appears from our data that the tetrapeptide  $\gamma$ -oxycarbonyl-L-valyl-L-valyl-L-alanylglycine ethyl ester (I) has a secondary structure in chloroform, in methanol, and even in hexafluoroacetone sesquihydrate (A). Only in 0.5 M KF in HFA does I seem to have no secondary structure.

The amino acid structure of I corresponds to the sequence 133–136 of the  $\beta$  chain of human hemoglobin. This occurs at approximately the center of helix 1 of the  $\beta$  chain, a long helical segment which extends to the carboxyl terminus of the native polypeptide.<sup>3</sup> Tripeptide I was synthesized in a stepwise manner by the dicyclohexylcarbodiimide<sup>4</sup> method. Carboxy-L-alanine and glycine ethyl ester hydrochloride and carbobenzoxy-L-alanylglycine ethyl ester,<sup>5</sup> mp 103°, which was treated with hydrogen bromide in glacial acetic acid and coupled with carbobenzoxy-L-alanine to give carbobenzoxy-L-valyl-L-alanylglycine ethyl ester, mp 192–192.5°,  $[\alpha]_D^{25} +5^\circ$  (c 2.0, dimethylamide). This tripeptide was similarly treated to the crystalline tripeptide L-valyl-L-alanylglycine ethyl ester hydrobromide, mp 181.5–182°,  $[\alpha]_D^{25} +33^\circ$  (c 0.5, water), which was coupled with *t*-butoxy-carbonyl-L-valine to give I, mp 212–213°,  $[\alpha]_D^{25} +77^\circ$  (c 0.5, methanol). Anal. Calcd for  $C_{22}H_{40}N_4O_7$ : C, 55.94; H, 8.53; N, 11.86. Found: C, 55.94; H, 8.53; N, 11.75.

Solutions of I in deuteriochloroform were examined in the infrared at concentrations from  $1.45 \times 10^{-2}$  M to  $1.45 \times 10^{-5}$  M. The absorption band at 3300  $\text{cm}^{-1}$  due to hydrogen-bonded N–H showed an increase on the first tenfold dilution, so that its intensity at  $1.45 \times 10^{-5}$  M was roughly half that at  $1.45 \times 10^{-2}$  M. However, the two subsequent dilutions produced no significant changes in the relative intensities of the 3300- and 3430- $\text{cm}^{-1}$  bands compared to the  $1.45 \times 10^{-2}$  M sample. This concentration-independent absorption indicates the presence of intramolecularly hydrogen bonded N–H.

The optical rotatory dispersion of I in the far-ultraviolet was found to show two troughs and a positive peak in both methanol and HFA (see Table I). In methanol, the troughs occurred at 235 and 205  $m\mu$  with a peak lying below 200  $m\mu$ . A similar curve was obtained in HFA: troughs at 227 and 205  $m\mu$  and the peak again below 200  $m\mu$ . On examination of the data in 0.5 M KF in HFA, the trough at ca. 230  $m\mu$  was no longer present. The trough at 205  $m\mu$  and a peak at 189  $m\mu$  were the only distinguishable features. With molecular models, one can build three structures

for I with internal hydrogen bonds. One of these represents the beginning of an  $\alpha$  helix and allows formation of a single intramolecular bond. The differences between the other two appear to be slight, and both allow formation of two hydrogen bonds. Structure I (Figure 1) corresponds to the folded, antiparallel  $\beta$ -sheet conformation proposed by Schwyzer<sup>6</sup> for cyclization of hexapeptides. The other, structure II (Figure 2), is the  $3_{10}$  helix of Bragg, Kendrew, and Perutz<sup>7</sup> after Huggins.<sup>8</sup> Our models appear to allow either a left-

handed or a right-handed screw sense in the  $3_{10}$  structure.

The trough at 235  $m\mu$  observed for I in methanol suggests the 233- $m\mu$  minimum found for  $\alpha$ -helical polypeptides,<sup>9</sup> while the 227- $m\mu$  trough in HFA suggests the minimum found for certain proteins thought to have the  $\beta$ -sheet structure.<sup>10</sup> The 205- $m\mu$  trough found in all our systems is probably the same as that found for the random-coil<sup>9</sup> structure of polypeptides.

The mean residue rotations observed for small peptides at the extrema of the optical rotatory dispersion curves have been found to be much smaller than in the cases for high molecular weight polyamino acids. This is to be expected, since the amide groups involved in intramolecular hydrogen bonding in these peptides are so engaged on only one of their sides,<sup>2</sup> leaving the other free to interact with solvent. Our data on dipeptides and tripeptides are similar in nature but do not indicate the presence of such secondary structure as has been found for tetra- and higher peptides.<sup>2</sup>

## Metalated Carboxylic Acids. I. Alkylation

Sir:

Aliphatic carboxylic acids and their salts have not been reported to metalate by a simple, generalized process on treatment with Grignard reagents,<sup>1</sup> organolithium reagents,<sup>2,3</sup> or alkali metal amides.<sup>4</sup> Except for salts of acetic acid<sup>4a</sup> and methacrylic acid,<sup>4b</sup> homologous metalated carboxylic acid salts apparently decompose under conditions used for their formation.<sup>4a</sup> Arylacetic acids, as well as their salts and simple carboxyl derivatives, are exceptional in that they produce "Ivanov" reagents on treatment with Grignard reagents or "Ivanov-like" reagents on treatment with other organometallic agents.<sup>5</sup> Phenylacetic acid has been metalated also with sodium (potassium) amide in ammonia.<sup>6</sup> This communication reports the metalation of aliphatic carboxylic acids to be a general

R. Ellis, U. S. Patent 2,852,559 (1958); R. D. Closson and D. O. DePree, U. S. Patent 2,918,494 (1959).

(5) The terms "Ivanov" and "Ivanov-like" reagents apparently originated with F. F. Blicke and H. Raffelson, *J. Am. Chem. Soc.*, **74**, 1730 (1952). For a recent review see P. E. Wright, Ph.D. Dissertation, University of Michigan, 1959; *Dissertation Abstr.*, **21**, 3642 (1960).

(6) C. R. Hauser and W. J. Chambers, *J. Am. Chem. Soc.*, **78**, 4942 (1956); W. J. Chambers, W. R. Brasen, and C. R. Hauser, *ibid.*, **79**, 879 (1957).

phenomenon which is illustrated by the metalation of isobutyric acid<sup>7</sup> (1, R = CH<sub>3</sub>) on treatment with lithium diisopropylamide.

The addition of isobutyric acid, 1 (R = CH<sub>3</sub>), to lithium diisopropylamide, prepared from *n*-butyllithium and diisopropylamine, in tetrahydrofuran-heptane (hexane) at 0° produced 2 (R = CH<sub>3</sub>) in homogeneous solution. Metalated isobutyric acid, 2 (R = CH<sub>3</sub>), is apparently quite stable in the indicated solvent system at least up to 40°. The success of the metalation can be attributed in large measure to the use of lithium as metal, which, among other factors, confers favorable solubility on the metalated species.<sup>8</sup> Homogeneous solutions of 2 (R = CH<sub>3</sub>) of at least 1 *M* in tetrahydrofuran-heptane (hexane) (1:5, v/v) have been prepared. The existence of 2 (R = CH<sub>3</sub>) could be demonstrated by alkylation with *n*-butyl bromide (iodide) to produce 2,2-dimethylhexanoic acid in preparatively useful yields (Table I).

The alkylation of 2 (R = CH<sub>3</sub>) has synthetic utility for the preparation of highly hindered trialkylacetic acids. Several examples are illustrated in Table I. Useful yields were obtained for those alkyl halides that were not especially susceptible to elimination or related side reactions. The alkylation of dilithium derivative 2 (R = CH<sub>3</sub>) appears to be superior, even for such a sterically hindered example, to the alkylation of sodium sodioacetate<sup>9</sup> and more direct than most syntheses of trialkylacetic acids.<sup>10</sup> The yields of product are comparable to those obtained for the alkylation of lithioisobutyronitrile.<sup>11</sup> When 2 (R = CH<sub>3</sub>) was similarly treated with aliphatic dihalides, the tetramethyldicarboxylic acids listed in Table II were obtained.<sup>12</sup>

<sup>a</sup> Crude yield.

The utility of metalated carboxylic acids (2) for synthetic purposes can be partially illustrated with the following examples. Addition of 2-methylbutyric acid, 1 ( $\text{R} = \text{C}_2\text{H}_5$ ), to lithium diisopropylamide as above produced 2 ( $\text{R} = \text{C}_2\text{H}_5$ ) in homogeneous solution. Subsequent addition of *n*-butyl bromide gave 2-ethyl-2-methylhexanoic acid (76%) on acidification and distillation.<sup>13</sup> Alkylation of 2 ( $\text{R} = \text{CH}_3$ ) with 2,3-dichloropropene yielded 4-chloro-2,2-dimethyl-4-pentenoic acid (70%) which on hydrolysis in sulfuric acid<sup>14</sup> conveniently produced 2,2-dimethyllevulinic acid (98%). Finally, to illustrate the reaction of metalated carboxylic acids with epoxides, treatment of 17 $\beta$ ,20-epoxy-17 $\alpha$ -methyl-5-androsten-3 $\beta$ -ol (4)<sup>15</sup> with excess 2 ( $\text{R} = \text{CH}_3$ ) at 40° produced spiro lactone 5 (81%).

(13) R. E. Pincock and J. H. Rolston, *J. Org. Chem.*, **29**, 2990 (1964), obtained 38% of the ethyl ester by alkylation with *n*-butyl bromide.

## Acid-Catalyzed Ester Hydrolysis

Sir:

The mechanism of acid-catalyzed hydrolyses of ordinary esters is most frequently represented as occurring *via* water attack on preprotonated esters. Because the concentration of protonated ester is minute in aqueous

solutions of dilute acids, general acid catalyzed attack of water possibly *via* a cyclic transition state has been proposed as an attractive alternative pathway.<sup>1</sup> An attempt is made in this article to assess whether the activation produced by protonation of a small fraction of ester molecules is sufficient to account for observed hydrolysis rates in weakly acid solutions. A comparison is made between the specific rate constant for water attack on protonated esters and that calculated from hydrolysis rates of esters chelated to transition metal ions.

Observed second-order rate constants for acid hydrolysis of ordinary esters such as ethyl acetate<sup>2</sup> at 25° are about  $10^{-4} \text{ M}^{-1} \text{ sec}^{-1}$ . When these constants are multiplied by the acid ionization constants of about  $10^{-5} \text{ M}$  for carboxylic acids and esters,<sup>3</sup> a first-order rate constant of about  $10^{2.5} \text{ sec}^{-1}$  is calculated for the rate of water attack upon protonated esters in aqueous solutions. Protonation of esters is known to occur at the carbonyl oxygen.<sup>4</sup> If the species with a protonated ether oxygen is advanced as the kinetically active one, its greater acid ionization constant decreases the concentration of kinetically significant protonated species which must be compensated by a correspondingly greater reactivity.<sup>5</sup> In this research,  $10^{2.5} \text{ sec}^{-1}$  is taken as the rate of water attack on the kinetically significant carbonyl oxygen protonated ester. The remainder of this paper attempts to determine whether this rate constant is reasonable.

An estimate may be made of the hydrolysis rate to be expected from placement of a positive charge on the carbonyl oxygen atom from two studies of transition metal ion catalyzed glycine ethyl ester hydrolysis. At 25° the first-order rate constant for water attack upon the dipositive cupric ion complex of glycine ethyl ester<sup>6</sup> is  $4.3 \times 10^{-5} \text{ sec}^{-1}$ . The corresponding value for water attack upon N-protonated glycine ethyl ester<sup>6</sup> is  $5 \times 10^{-9} \text{ sec}^{-1}$ . Since the rate for the cupric complex exceeds the last figure by almost  $10^4$ , while the effect predicted for an increase of unit positive charge at the nitrogen atom is less than  $10^2$ , hydrolysis in the cupric ion case proceeds *via* a chelated ligand with the transition metal ion positive charge located at the carbonyl oxygen. A similar argument for chelation has been presented for hydroxide ion attack at protonated and cupric ion complexes of glycine ethyl ester.<sup>6</sup> Though hydrolysis proceeds *via* a chelated cupric ion complex, it is not known to what extent the carbonyl oxygen is chelated to the cupric ion, the primary binding site of which is at the amino nitrogen.<sup>6</sup> Complete chelation might serve to increase the rate constant if it represents a value for a condition where the complexes are not chelated most of the time. It has been established that glycine ethyl ester is virtually completely chelated in the cobaltic complex  $[\text{Co}(\text{NH}_2\text{CH}_2\text{CH}_2\text{NH}_2)(\text{NH}_2\text{CH}_2\text{COOC}_2\text{H}_5)]^{3+}$ . At 25° the first-order rate constant for ester hydrolysis due to water attack

(6) H. L. Conley, Jr., and R. B. Martin, *J. Phys. Chem.*, **69**, 2914 (1965).

upon this tripositive complex<sup>7</sup> is  $7.2 \times 10^{-3} \text{ sec}^{-1}$ , about 170 times faster than for the dipositive cupric complex. That this factor is about twice as large as might be predicted from the difference of one unit of positive charge in the two transition metal ion complexes may be due to only about half the cupric complexes being chelated at any one time or to a greater polarizing power for cobaltic ion at the carbonyl oxygen.

The rate constant from the second paragraph of  $10^{2.5} \text{ sec}^{-1}$  for water attack at carbonyl oxygen protonated ester of unit positive charge exceeds by  $10^{6.9}$  and  $10^{4.6}$  the respective rate constants for water attack of  $10^{-4.4} \text{ sec}^{-1}$  at the dipositive cupric chelate and  $10^{-2.1} \text{ sec}^{-1}$  at the tripositive cobaltic chelate of glycine ethyl ester. On the basis of the argument so far presented, the large rate advantages for the protonated ester over the transition metal ion chelates suggest that acid-catalyzed ester hydrolysis proceeds much too rapidly to be accounted for by water attack on the small concentrations of preprotonated ester existing in weakly acid solutions. The argument presented is an electrostatic one based on considerations of specific rate constants of species of known charge distribution. It is generally recognized, however, that the polarizing power of the proton even when hydrated is greater than that of metal ions in similar solvents. It is necessary, therefore, to attempt an estimate of the relative charge densities at the carbonyl carbon, where water attack takes place, due to the different polarizing powers of the hydrated proton and cupric or cobaltic ions located at the carbonyl oxygen atom.

The relative  $\sigma$ -bond polarizing powers due to the hydrated proton and cations at an atom attached to oxygen may be estimated from the acid ionization constants for loss of a proton from their respective hydration spheres according to eq 1, where  $\text{H}^+$  is an abbrevi-

ation for the hydrated proton. For M as  $\text{H}^+$ ,  $\text{Cu}^{2+}$ , and  $\text{Co}^{2+}$ , the respective  $pK_a$  values<sup>8</sup> for eq 1 are -1.7, 7.3, and 1.7, indicating that the polarizing power of the proton is about  $10^{9.0}$  and  $10^{3.4}$  times greater than for the aquo metal cations. However, when cobaltic ion is combined with five nitrogen donors, its polarizing power appears much decreased since for eq 2  $pK_a$ <sup>8</sup> is 6.2. A steady increase in  $pK_a$  for ionization from water

occurs as nitrogen is substituted for oxygen donors about the cobaltic ion.<sup>8</sup> The hydrated proton appears to be  $10^{7.9}$  times more polarizing than cobaltic ion with five nitrogen donors. No corresponding information seems to be available for cupric ion where the  $pK_a$  for coordinated water ionization from a complex with one nitrogen donor is desired. Allowing one log unit per nitrogen donor, we may estimate the hydrated proton to be  $10^{10}$  times more polarizing than cupric ion with one nitrogen donor.

(8) "Stability Constants," Special Publication, No. 17, The Chemical Society, London, 1964.

Rate constants for water attack at carbonyl oxygen protonated esters may now be calculated by multiplying the rate constant for water attack at each metal ion chelate of glycine ethyl ester by the relative polarizing powers of hydrated proton and cation. We obtain for the cobaltic chelate,  $10^{-2.1} \times 10^{7.9} = 10^{5.8} \text{ sec}^{-1}$  and for the cupric chelate,  $10^{-4.4} \times 10^{10} = 10^{5.6} \text{ sec}^{-1}$ . These values are about  $10^{3.2}$  times greater than the experimental value of  $10^{2.5} \text{ sec}^{-1}$  so that this last rate constant appears to be an attainable one. We conclude that acid-catalyzed hydrolysis of ordinary esters may well proceed by water attack on preprotonated ester.

Because of the symmetrical nature of ester hydrolysis and formation reactions<sup>9</sup> and the similar values of carboxylic acid and ester ionization constants<sup>3</sup> as suggested by their comparable dipole moments,<sup>10</sup> the conclusion advanced here is applicable to the formation as well as the hydrolysis reaction. Partitioning of the tetrahedral carbon addition intermediate to yield ester or acid is comparable in both acid<sup>11</sup> and metal ion<sup>12</sup> catalyzed reactions so that the conclusions are not affected by a change in the rate-limiting step.

## N-Sulfonylamines

Sir:

We wish to report the generation of a new class of electrophilic amine derivatives designated as N-sulfonylamines ( $\text{RN}=\text{SO}_2$ ). Unlike the related N-sulfinylamines<sup>1</sup> ( $\text{RN}=\text{S}=\text{O}$ ), the N-sulfonylamines studied so far appear to be stable only at low temperature in solution. Ethylsulfamoyl chloride<sup>2</sup> (II) reacts rapidly with 1 equiv of triethylamine in toluene solution at  $-78^\circ$  to afford a nearly quantitative yield of precipitated triethylamine hydrochloride. Filtration at this temperature provides solutions of I, which undergoes mildly exothermic polymerization upon warming. Successful interception of the N-sulfonylethylamine was accomplished by the addition to this solution of a nucleophile such as aniline which results in a 21% yield of N-phenyl-N'-ethylsulfamide (III).<sup>3,4</sup>

(1) G. Kresze, *et al.*, *Angew. Chem. Intern. Ed. Engl.*, **1**, 89 (1962).

(2) Prepared by the interaction of ethylamine hydrochloride and sulfonyl chloride in diethyl ether solution: N. C. Hansen, *Acta Chem. Scand.*, **17**, 2141 (1963); G. Schulze and G. Weiss, Belgian Patent 667,311 (1966).

(3) Identified by mixture melting point (where appropriate) and infrared spectral comparison with an authentic sample.

(4) A. Dorlars in Houben-Weyl's "Methoden der Organischen Chemie," Vol. 8, E. Muller, Ed., Georg Thieme Verlag, Stuttgart, Germany, 1952, pp 720-721.

generation of I at room temperature in the presence of 2-(dichloromethylene)-1,3-dioxalane<sup>5</sup> affords a quantitative yield of a cycloadduct, mp 74–75°, and the 1,2-thiazetidine 1,1-dioxide structure IV.<sup>6</sup>

Mass spectrum of IV displayed a molecular ion<sup>7</sup> at  $m/e$  262 and prominent ions at  $m/e$  107 ( $\text{C}_2\text{H}_5\text{N}^+$ ) and 154 ( $\text{C}_2\text{H}_5\text{SO}_2\text{Cl}_2^+$ ) resulting from 1,4 and 2,5 cleavage only; therefore our proposed orientation of this cycloadduct rests upon the mechanistic consideration that the transition state polarization of I is  $\text{S}^+\text{O}_2^-$ .

The electrophilic<sup>8</sup> N-sulfonylamines such as N-ethylbenzamide (V) were prepared in toluene solution at  $-78^\circ$  in an analogous manner from benzoylsulfonyl chloride.<sup>9</sup> The existence of V was likewise confirmed by the formation of N-benzoyl-N'-ethylthiazetidine<sup>3</sup> in 66% yield upon quenching with ethylamine at  $-78^\circ$ .<sup>10</sup>

Formation of V in the presence of excess ethylamine at  $30^\circ$  in benzene solution affords a 71% yield of a cycloadduct, mp 87–88°, for which structure VIII is proposed based on the following evidence. The mass spectrum ( $\text{CDCl}_3$ , 60 Mc) displayed quartets for  $\text{H}_\text{B}$  and  $\text{H}_\text{X}$  centered at  $\tau$  6.53, 6.20, and 4.07,

M. McElvain and M. J. Curry, *J. Am. Chem. Soc.*, **70**, 3781 (1948).

Satisfactory elemental analyses were obtained for all new compounds reported herein. The appearance of a  $\text{M} + 2$  and  $\text{M} + 4$  ion resulting from the isotopic combinations substantiated the dichloro assignment.

N-Sulfonylamine fails to react at room temperature with ethyl vinyl ether of low nucleophilicity such as ethyl vinyl ether. The reaction is prepared by the interaction of chlorosulfonyl isocyanate and ethylamine in benzene solution. See ref 4, p 700. Currently under investigation is the possibility that the reactive intermediate is the triethylamine adduct,  $\text{C}_6\text{H}_5\text{CON}^-\text{SO}_2\text{N}^+(\text{C}_2\text{H}_5)_3$ , as adducts of certain sulfenes have been reported recently by us and D. Bucher, *Tetrahedron Letters*, **43**, 5263 (1966).

respectively, with  $J_{\text{AB}} = 14$  cps,  $J_{\text{AX}} = 9$  cps, and  $J_{\text{BX}} = 3$  cps, and the molecular ion appeared at  $m/e$  255 in the mass spectrum. Treatment of VII with a benzene solution of triethylamine at  $30^\circ$  provided in nearly quantitative yield an isomer, mp 135–136°, assigned structure VIII.<sup>11</sup> The nmr spectrum ( $\text{CDCl}_3$ , 60 Mc) of VIII indicated a doublet for  $\text{H}_\text{X}$  centered at  $\tau$  4.08 coupled ( $J = 12$  cps) with  $\text{H}_\text{A}$ , whose absorption was superimposed on the aromatic and imide proton signals at  $\tau$  2.1–2.7. This evidence supports the structural assignment and establishes the orientation of the cycloaddition reaction leading to VII.

If a toluene solution of V at  $-78^\circ$  is allowed to warm to room temperature in the absence of a trapping agent exclusive rearrangement to phenyl isocyanate<sup>3</sup> occurs. It is interesting to speculate that this reaction may represent an  $\alpha$  elimination of sulfur dioxide, *i.e.*

Studies are in progress on the synthetic usefulness of N-sulfonylamines in elaborating small-ring heterocycles.

**Acknowledgment.** We wish to thank the National Institutes of Health for a predoctoral fellowship to G. M. A. and Dr. C. C. Sweeley of the University of Pittsburgh (Graduate School of Public Health) for the mass spectra.

(11) This imide was isolated as the triethylamine salt which was converted to VIII upon silica gel chromatography. This salt also results from the reaction of ethyl vinyl ether with VI in the presence of excess triethylamine.

## Photoreduction of Acetone by Tributylstannane

Sir:

The intermediacy of the triplet states of ketones in their photoreductions is so well established<sup>1–3</sup> that there has been some doubt whether the corresponding excited singlet states have any chemical reactivity in bimolecular reactions in solutions. When it became clear that aliphatic ketones undergo type-II photoelimination from both singlet and triplet excited states,<sup>4</sup> we suggested<sup>5</sup> that the  $n, \pi^*$  excited singlet states of carbonyl compounds may in general be just as reactive

as the corresponding triplet states but not undergo bimolecular reactions simply because the competing intersystem-crossing process is too rapid. If a bimolecular singlet-state photoreaction is to be observed, it seems obvious that both a very reactive substrate and a ketone with a low rate of intersystem crossing are necessary. Consequently, the photoreduction of acetone by tri-*n*-butylstannane has been studied.

Degassed hexane solutions containing 0.75 *M* acetone, 0.005 *M* fluorobenzene as internal standard, 0.38 *M* freshly prepared tri-*n*-butylstannane, and various concentrations of 2,5-dimethyl-2,4-hexadiene (0–0.10 *M*) or 1,3-pentadiene (5 *M*) were subjected to equal intensities of 3130-Å radiation. Quantum yields of 2-propanol formation were then determined by glpc analysis. Quite unexpectedly, it developed that a slow dark reaction produces isopropyl alcohol, or at least a compound with the same retention time on a FFAP glpc column, even in the presence of diene. It was at first assumed incorrectly that this unquenchable alcohol formation indicated some singlet photoreduction. However, in experiments in which analysis was performed immediately after irradiation, only traces of alcohol could be detected in samples containing 5 *M* diene and as much as 1.5 *M* stannane. Photochemical conversion of acetone to 2-propanol proceeded with unit quantum yield in samples containing no quencher. The 2-hydroxy-2-propyl radical initially formed apparently abstracts a hydrogen atom from a second stannane molecule with very high efficiency. In solutions containing 5 *M* diene, the quantum yield of 2-propanol formation was <0.01 for both 0.38 and 1.5 *M* stannane. Moreover, the quantum yield of acetone disappearance was negligible at high perylene concentrations, indicating that the dienes quench by triplet energy transfer rather than by trapping of intermediate radicals. The possibility of singlet quenching is eliminated by our observation<sup>4</sup> that singlet type-II reactions are not quenched by dienes and by Rebbert and Ausloos' report that dienes do not quench the fluorescence of acetone.<sup>6</sup> Stern–Volmer plots of relative quantum yields yielded a straight line, with a slope equal to  $k_q/0.38k_{th}$ , where  $k_q$  is the bimolecular rate constant for quenching and  $k_{th}$  is the bimolecular rate constant for hydrogen abstraction from the stannane by triplet acetone. The values of the slope were 32.5 and 29.1  $M^{-1}$  in two separate runs.

That acetone should be photoreduced only from its triplet state by moderately high concentrations of tri-*n*-butylstannane becomes quite striking when the magnitudes of the relevant rate constants are considered. A 10% hexane solution of the stannane is only slightly more viscous than hexane itself, so that  $k_q$  can be estimated to equal  $1 \times 10^{10} M^{-1} \text{sec}^{-1}$ .<sup>5</sup> The value of  $k_{th}$  thus indicated by the Stern–Volmer slopes is  $8 \times 10^8 M^{-1} \text{sec}^{-1}$ . This very large number is not too surprising in view of the ability of the stannane to photoreduce acynaphthalenes<sup>2</sup> and greatly exceeds the measured rate of decay of triplet acetone in hexane alone,<sup>3,7,8</sup>  $1 \times 10^6 \text{sec}^{-1}$ . The actual rate of reaction of triplet acetone with 0.38 *M* stannane is  $3.2 \times 10^8$

$\text{sec}^{-1}$ . If the rate of intersystem crossing (isc) of acetone is  $4 \times 10^7 \text{sec}^{-1}$ ,<sup>9</sup> and if singlet acetone were just as reactive as triplet acetone, then a quantum yield of unquenchable singlet photoreduction equal to 0.89 ought to be observed. However, since  $\Phi_S < 0.01$ , even at 1.5 *M* stannane concentration,  $k_{th} < 0.01 k_{isc}$ . Borkman and Kearns estimated  $k_{isc}$  as  $4 \times 10^7 \text{sec}^{-1}$  from the integrated absorption intensity of acetone and from their measured fluorescence quantum yield in solution of 0.01.<sup>9</sup> Heicklen and Noyes have reported that the quantum yield of acetone fluorescence in the gas phase at 40° is 0.002.<sup>10</sup> There is no reason to suspect that the radiative lifetime estimated from the integrated absorption intensity is in error by more than a factor of 2,<sup>11</sup> and thus it does not seem likely that  $k_{isc}$  for acetone exceeds  $2 \times 10^8 \text{sec}^{-1}$ . Nor does it seem possible that the stannane might be producing a heavy-atom enhancement of  $k_{isc}$ , since theory predicts<sup>12</sup> and experiment confirms<sup>13</sup> that  $n, \pi^*$  excited states are not very susceptible to heavy-atom effects. If  $k_{th}$  were to equal  $k_{th}$ ,  $k_{isc}$  would have to equal at least  $10^{11} \text{sec}^{-1}$ . It seems much more likely that the lack of singlet-state reaction is caused by  $k_{th}$  being smaller than  $10^6 M^{-1} \text{sec}^{-1}$ , so that it must be concluded that *excited singlet acetone is appreciably less reactive than triplet acetone*.

If excited singlet acetone is only  $1/1000$  as reactive as triplet acetone in hydrogen-abstraction reactions, such should be the case with other aliphatic ketones, in which case the already mentioned intermediacy of both excited states in type-II processes<sup>4,5</sup> requires a new explanation. From the measured singlet-state quantum yields and triplet-state lifetimes of 2-pentanone and of 2-hexanone,<sup>4,5</sup> an assumption of equal reactivity in both states yields an estimate of  $3 \times 10^9 \text{sec}^{-1}$  for  $k_{isc}$ . This value is larger than what might have been extrapolated from the published value for acetone<sup>9</sup> but convincingly smaller than the value for acetone which results from the assumption of equal singlet and triplet state reactivity. Fortunately, it remains highly possible that type-II photoelimination may proceed by different mechanisms in the two excited states, namely by a concerted six-center process in the singlet and by a perhaps faster intramolecular hydrogen abstraction in the triplet.

There is no good theoretical explanation for  $n, \pi^*$  excited states of different multiplicities having different reactivities, and as long ago as 1958 Robinson predicted from a high-resolution spectroscopic investigation of formaldehyde that the two states should have similar reactivities.<sup>14</sup> The prediction was based on the very similar electronic distribution in the two excited states. However, with a little hindsight it might be noted that triplet formaldehyde—and presumably other carbonyl compounds—comes much closer to assuming a pyramidal (tetrahedral) geometry than does the singlet state.<sup>14</sup> Walling and Gibian have demonstrated the close parallel between the reactivities of

### 1-Chlorobicyclopropyl. Evidence for the Formation of a Cyclopropyl Propanol during the Hydrolysis of a Cyclopropyl Halide

We wish to report unprecedented examples of solvolyses of a simple cyclopropyl derivative which result in products that arise from the attack of solvent on an intermediate ion in which the cyclopropane ring is intact.

Because of the facile rearrangement of the cyclopropyl to the allyl carbonium ion, the only products that have ever been observed in the solvolyses of monosubstituted cyclopropyl derivatives have been open-chain allylic structures.<sup>1,2</sup>

Although reports have appeared that the nitrous acid deamination of apotricyclylamine (1),<sup>3</sup> 1-aminocyclohexene (2),<sup>4</sup> and 3-amino-1,2-cyclopropanoacene (3)<sup>5</sup> resulted in unrearranged products, the

(c) Lipp and C. Padberg, *Chem. Ber.*, **54B**, 1316 (1921).

(d) Hart and R. H. Martin, *J. Am. Chem. Soc.*, **82**, 6362 (1960).

(e) Pettit, *ibid.*, **82**, 1972 (1960).

explanation for the lack of rearrangement has been based either on considerations of orbital symmetry during the electrocyclic transformation to the allylic structure<sup>2b,6</sup> or on the assumption that the mechanism may have been free radical in nature<sup>7</sup> rather than involving a carbonium ion.<sup>8</sup>

In the present study, 1-chlorobicyclopropyl (4) was prepared in an over-all yield of 30–44% by vapor phase chlorination of the parent hydrocarbon followed by distillation of the monochloride product fraction which contained about 89% of the desired material.<sup>9</sup>

The acetolysis of chloride 4 in the presence of silver acetate at 115° for 72 hr produced a mixture of products from which a 42.6% component was isolated and identified as the unrearranged 1-acetoxibicyclopropyl (5). A direct infrared spectral comparison with a sample prepared by the addition of dibromocarbene to the enol acetate of methyl cyclopropyl ketone, followed by reduction of the resulting dibromoacetate 6 with tri-*n*-butyltin hydride, confirmed the assignment of structure.<sup>10</sup> In a similar experiment, the silver ion assisted hydrolysis of 4 (65°, 24 hr) produced a mixture of several compounds, of which the major component (65%) was identified as ethyl cyclopropyl ketone (8) by spectral comparison of the collected peak (vpc) with an authentic sample. No other single component of the product mixture represented more than 24%.<sup>11</sup> In view of the acetolysis results, the

presence of ketone 8 as the major product can be readily explained by assuming that 1-bicyclopropanol (7) is formed initially and then undergoes an acid-catalyzed ring opening to the ketone, the latter reaction having been well established for a variety of 1-substituted cyclopropanols.<sup>12</sup> If instead of undergoing an attack by water, the initially formed carbonium ion had opened to produce the allylic ion, a process of the type which occurs to the exclusion of all others during the solvolyses of other cyclopropyl derivatives, the expected product would have been  $\beta$ -cyclopropylallyl alcohol, a compound which may yet be identified as a minor constituent of the product mixture.

(6) S. J. Cristol, R. M. Sequeira, and C. H. DePuy, *ibid.*, **88**, 4007 (1966); R. B. Woodward and R. Hoffman, *ibid.*, **87**, 395 (1965).

(7) K. V. Scherer, Jr., and R. S. Lunt, III, *ibid.*, **88**, 2860 (1966).

(8) In the original explanation of the behavior of 2 and 3 by Hart,<sup>4</sup> it was assumed that the unrearranged product formed from the collapse of a diazonium ion pair directly to the product.

(9) Chloride 4 gave the correct analysis for  $\text{C}_6\text{H}_7\text{Cl}$  and an nmr spectrum consistent only with the assigned structure.

(10) The nmr spectrum of 5 showed only complex multiplets from  $\tau$  8.0 to 8.6 and 9.0 to 9.9 and a sharp singlet at 8.1.

(11) Several other products have only been tentatively identified and will be discussed in detail in a subsequent publication.

(12) C. H. DePuy, F. W. Breitbeil, and K. R. DeBruin, *J. Am. Chem. Soc.*, **88**, 3347 (1966), and references cited therein.

That the ion formed initially during the hydrolysis of 4 had considerable charge delocalization is suggested by considering a comparison of the solvolysis rate of 4 in aqueous ethanol<sup>13</sup> with that of cyclopropyl chloride (Table I). Although a direct comparison of

Table I. Solvolysis Rates of Selected Cyclopropyl Derivatives

Compound	Temp, °C	Solvent	k, sec <sup>-1</sup>
Cyclopropyl chloride	95	50% EtOH	$2.5 \times 10^{-10}$ <sup>a</sup>
1-Chlorobicyclopropyl	95	50% EtOH	$1.58 \times 10^{-10}$ <sup>b</sup>
Cyclopropyl bromide	130	50% EtOH	$2.6 \times 10^{-6}$ <sup>c</sup>
1-Methylcyclopropyl bromide	130	50% EtOH	$1.05 \times 10^{-4}$ <sup>c</sup>
Cyclopropyl tosylate	108	HOAc	$1.5 \times 10^{-7}$ <sup>d</sup>
1-Phenylcyclopropyl tosylate	108	HOAc	$1.93 \times 10^{-2}$ <sup>a</sup>

<sup>a</sup> Extrapolated data from ref 1; see J. A. Landgrebe and D. E. Applequist, *J. Am. Chem. Soc.*, **86**, 1536 (1964). <sup>b</sup> This work. <sup>c</sup> E. F. Cox, M. C. Caserio, M. S. Silver, and J. D. Roberts, *J. Am. Chem. Soc.*, **83**, 2719 (1961). <sup>d</sup> Extrapolated from data in ref 1. <sup>e</sup> Reference 2b.

all the numerical values in the table is not possible because of the variety of solvents, temperatures, and leaving groups employed by various workers, it seems clear that the introduction of a cyclopropyl group into the 1 position of cyclopropyl chloride has a very large accelerating effect compared with the introduction of a 1-methyl or even a 1-phenyl group on cyclopropyl bromide and tosylate, respectively. Extensive charge delocalization in the ion formed initially during the solvolysis of 4 would be expected on the basis of the well-known behavior of the cyclopropyl-carbinyl system<sup>14</sup> and is undoubtedly responsible for the unique solvolysis behavior of chloride 4. Further studies on systems of this type are in progress.<sup>15</sup>

(13) A substantial amount of ketone 8 was also formed during the solvolysis of 4 in 50 vol. % aqueous ethanol, i.e., under the conditions of the kinetic study. Most if not all of the other silver ion assisted hydrolysis products appear to be present as products of the aqueous ethanolysis.

## The Synthesis of Ajmaline<sup>1</sup>

Sir:

Numerous naturally occurring ajmaline-sarpagine type alkaloids<sup>2</sup> are structurally characterized by the presence of the quinuclidine ring and the C<sub>6</sub> and C<sub>16</sub>

bond linkage, e.g., ajmaline (1) and sarpagine (2).<sup>3</sup> Since the structural elucidation of ajmaline by Woodward<sup>4a</sup> and Robinson,<sup>4b</sup> the unique features of the alkaloids have presented a considerable challenge to synthetic organic chemists. We describe herein the first total synthesis of ajmaline.

Condensation<sup>5</sup> of the magnesium chelate of ethyl hydrogen Δ<sup>3</sup>-cyclopentenylmalonate<sup>6</sup> with N-methyl-3-indolylacetyl chloride, mp 9–11°, provided in 80% yield a keto ester (3), mp 20–23°. Reaction of 3 with methoxyamine followed by lithium aluminum hydride afforded in 70% yield an approximately 2:1 mixture of readily separable epimeric α,γ-amino alcohols 4 [diacetyl derivative, mp 140–141°; dibenzoyl derivative 5, amorphous] and 4a, mp 113.5–114.5° [diacetyl derivative, mp 117–118°; dibenzoyl derivative 5a, mp 170–172°]. These epimeric series of compounds are both useful for the synthesis of natural products, and they are interconvertible at a later stage of the synthesis (*vide infra*). Treatment of 5 and 5a with osmium tetroxide and then sodium metaperiodate afforded quantitatively aldehydes 6 and 6a,<sup>7</sup> which were warmed with acetic acid at 50° for 1 hr to give tetracyclic aldehydes 7 and 7a in 40 and 50% yield, respectively. Structures 7 and 7a were compatible with spectral data<sup>8</sup> of the respective compounds and

(3) W. I. Taylor, *Alkaloids*, **8**, 785 (1965).

(6) Prepared from the corresponding diethyl ester: C. C. Lee and E. W. C. Wong, *Tetrahedron*, **21**, 539 (1965).

(7) The preparation of dialdehydes by this procedure was utilized in earlier indole alkaloid syntheses: (a) E. E. van Tamelen, M. Sharma, A. W. Burgstahler, J. Wolinsky, R. Tamm, and P. E. Aldrich, *J. Am. Chem. Soc.*, **80**, 5006 (1958); (b) E. E. van Tamelen, L. J. Dolby, and R. G. Lawton, *Tetrahedron Letters*, No. 19, 30 (1960).

(8) Spectral data included ultraviolet, infrared, nmr, and mass spectra. Compounds with no description of melting points have been amorphous. These compounds were purified until each gave a single spot on thin layer chromatography, using several solvent systems. All new crystalline compounds gave satisfactory elemental analyses.

characterized by converting them in more than one way into the corresponding dihydroxy secondary amine 7', mp 208–209°, and 7a', mp 162–163°, with aluminum hydride and then catalytic hydrogenation.

Conversion of 7 into the cyano compound 8 was achieved by treatment with hydroxylamine and benzoyl chloride in warm pyridine. The compound 8 (triphenylmethylsodium-tetrahydrofuran) reacted with excess ethyl iodide to provide in 70% monoethyl compounds, from which a pure ethyl compound 9<sup>8</sup> was isolated in 60–70% yield. Treatment of 9 with sodium methoxide removed the benzoyl group from the ester to give a hydroxy compound (10), mp 202.5–204.5°. Similarly, 8a was converted into 9a<sup>8</sup> and 10a.<sup>8</sup> Spectra<sup>8</sup> of 9, 10, 9a, and 10a were identical with those of the corresponding natural products of ajmaline, as shown below.

Compounds 7a, 7a', 8a, etc., are epimeric at C<sub>16</sub> with 7, 7', 8, respectively. Compounds 9 and 10 are racemates; 13 and 14 are *d* (or *l*) isomers.

Treatment of ajmaline oxime<sup>9</sup> with benzoyl chloride in warm pyridine followed by sodium hydroxide afforded a cyanobenzamide (11), mp 265–266°. Reduction of 11 with lead tetraacetate<sup>3</sup> followed by neutralization afforded an aldehyde (12), mp 219–220°,  $\tau$  0.45 (CHO) and 6.46 (N-CH<sub>3</sub>), which was reduced with sodium borohydride to the

corresponding hydroxy compound 13, mp 228–230° and 261–262°, O-benzoate (14).<sup>10</sup> In the presence of alumina 12 was equilibrated with its epimer, 12a; nmr (CDCl<sub>3</sub>, 60°)<sup>10</sup>  $\tau$  0.32 (CHO) and 6.54 (N-CH<sub>3</sub>), in a 3:7 ratio in favor of 12a. Thus 12 and 12a were interconvertible. The sodium borohydride reduction of 12a provided a hydroxy compound (13a) which was converted with hydrochloric acid to a lactone (15), mp 312–313°. Compounds 13 and 13a were oxidized with dimethyl sulfoxide and acetic anhydride (or carbodiimide)<sup>11</sup> to afford 12 and 12a, respectively. Identity of spectral data<sup>8</sup> of 13, 14, 13a, and 14a with those of 10, 9, 10a, and 9a, respectively, established the structures and stereochemistry of synthetic intermediates.

Compound 12 upon treatment with hydrochloric acid in acetic acid and acetic anhydride underwent cyclization to afford in 65% yield compound 16, which was hydrogenated with platinum catalyst in 6*N* hydrochloric acid to yield in 60% yield compound 17, mp 202–204°, and the corresponding 2 epimer in 30% yield.<sup>12,13</sup> Reduction of 17 with lithium triethoxyaluminum hydride provided the corresponding benzyl derivative 18, mp 170.5–171.5°, which was in turn hydrogenolyzed to a secondary amine (19), mp 260–262°. Since 19 has already been converted into 1 with lithium aluminum hydride,<sup>9</sup> we have completed the first synthesis of ajmaline.<sup>14</sup>

**Acknowledgment.** The authors are grateful to the National Research Council of Canada for financial support.

(11) A. H. Fenselau and J. G. Moffatt, *J. Am. Chem. Soc.*, **88**, 1762 (1966), and references cited therein.

(12) Compound 16 existed exclusively in the indoleninium form under these conditions:  $\lambda_{\text{max}}^{\text{NHCl}}$  294 m $\mu$  ( $\epsilon$  7200), 244 (11,700), and 236 (13,200).

(13) Catalytic hydrogenation of 21-deoxyajmalin-A<sup>3</sup> and 2-hydroxyvincamedine under acidic conditions proceeded from the  $\alpha$  side of the compounds to yield 2-*epi* series of ajmaline type compounds [J. Gosset-Garnier, J. Le Men, and M.-M. Janot, *Bull. Soc. Chim. France*, 676 (1965)]. Dreiding models of these compounds reveal that the  $\alpha$  and  $\beta$  sides present only a slight difference in steric hindrance toward hydrogenation. The exclusive  $\alpha$  attack reported above was presumably due to the presence of the protonated nitrogen atom in the  $\alpha$  side. In accord with this view, 16, in which the amine was benzoylated, provided predominantly a compound of the normal series.

(14) Compound 15 was readily converted into N-methyl-10-desoxydihydrosarpagine<sup>3</sup> through a sequence of four steps in 35% over-all yield.

### The Stereospecific Introduction of a Vicinally Functionalized Angular Methyl Group. A Synthesis of *l*-Valeranone

Sir:

The molecular rearrangement accompanying the transformation of  $\beta$ -diketones and related substances into monoketones by the action of zinc and acid has been interpreted in terms of reductive formation of cyclopropanols followed by acid-induced ring cleavage.<sup>1</sup>

(1) (a) E. Wenkert and E. Kariv, *Chem. Commun.*, 570 (1965); (b) B. R. Davis and P. D. Woodgate, *J. Chem. Soc.*, 2006 (1966), and references therein.

A. L. Anet, D. Chakravarti, R. Robinson, and E. Schlittler, *J. Am. Chem. Soc.*, **77**, 1242 (1954). All compounds containing the benzamide group showed temperature-dependent nmr spectra.

The high specificity of protolysis of a fused, polycyclic methoxycyclopropane recently isolated from a Clemmensen reduction (in methanol solution) which had been quenched at an early stage ( $a \rightarrow b$ )<sup>2</sup> strongly recommended the use of cyclopropyl ethers in organochemical synthesis in general and for the construction of quaternary carbon sites next to oxygenated carbon centers in particular. We now wish to report a seven-step synthesis of *l*-valeranone (I)<sup>3</sup> whose biosynthetically anomalous  $\alpha$ -methylketo moiety (encircled structural unit in I) made this sesquiterpenic ketone an ideal object for exploitation of the new synthetic procedure.<sup>4</sup>

Condensation of *d*-carvomenthone with 1,4-dimethoxy-2-butanone,<sup>5</sup> the *in situ* precursor of methoxymethyl vinyl ketone,<sup>6,7</sup> under the influence of ethanolic potassium hydroxide in ether solution<sup>8</sup> produced a mixture of ketol and isomeric enones, predominating (4.5:1) in the  $10\alpha$ -methyl configuration, from which the liquid ketol IIa [36%; infrared (neat): 2.90 (OH, m), 5.81  $\mu$  (C=O, s); pmr (CDCl<sub>3</sub>): one-proton singlet at  $\delta$  3.99 (methoxymethine), three-proton singlet at 3.50 (methoxyl), 1.25 (angular Me), six-proton broad doublet at 0.83 ( $J$  = 6.0 cps, isopropyl methyls). *Anal.* Found: C, 70.94; H, 10.40] could be isolated. The structure of this ketol was determined by its conversion into the demethoxy derivative IIb [79%; infrared (neat): 2.84 (OH, m), 5.85  $\mu$  (C=O, s). *Anal.* Found: C, 74.37; H, 10.70] on lithium-ammonia reduction, followed by transforma-

tion of the latter on acid-induced dehydration<sup>9</sup> into the unsaturated ketone IIIb (91%, mp 28–28.5°) whose optical rotatory dispersion curve was the mirror image of the known enantiomer.<sup>10</sup> The ketones IIb and IIIb also were the products of a base-catalyzed condensation<sup>8</sup> of *d*-carvomenthone and methyl vinyl ketone.

Treatment of the ketol IIa with ethanolic potassium hydroxide yielded the enone IIIa [78%;  $[\alpha]^{21}_D$  -163° ( $c$  1.0, CHCl<sub>3</sub>); infrared (neat): 5.96 (C=O, s), 6.21  $\mu$  (C=C, m);  $\lambda_{max}$  (EtOH) 257 m $\mu$  ( $\epsilon$  8500); pmr (CDCl<sub>3</sub>): three-proton singlet at  $\delta$  3.61 (methoxyl), 1.27 (angular Me), six-proton pair of doublets at 0.97, 0.87 ( $J$  = 5.5 cps, isopropyl methyls). *Anal.* Found: C, 76.21; H, 10.15] whose lithium aluminum hydride reduction produced the alcohol IV [94%;  $[\alpha]^{24}_D$  +25.7° ( $c$  1.2, CHCl<sub>3</sub>); infrared (neat): 2.99 (OH, m), 6.01  $\mu$  (C=C, m); pmr (CDCl<sub>3</sub>): one-proton multiplet at  $\delta$  4.44 (hydroxymethine), three-proton singlet at 3.58 (methoxyl), 1.14 (angular Me), six-proton pair of doublets at 0.94, 0.85 ( $J$  = 6.0 cps, isopropyl methyls). *Anal.* Found: C, 75.95; H, 10.71]. Simmons-Smith reaction<sup>11</sup> of this allyl alcohol<sup>12</sup> led to the cyclopropane derivative V [91%;  $[\alpha]^{21}_D$  -38.9° ( $c$  0.8, CHCl<sub>3</sub>); infrared (neat): 2.90 (OH, m), 3.25  $\mu$  (probably cyclopropyl H, w); pmr (CDCl<sub>3</sub>): one-proton multiplet at  $\delta$  4.34 (hydroxymethine), three-proton singlet at 3.36 (methoxyl), 0.92 (angular Me), six-proton broad doublet at 0.83 ( $J$  = 5.5 cps, isopropyl methyls), one-proton doublets at 0.66, 0.21 ( $J$  = 6.0 cps, cyclopropyl methylene). *Anal.* Found: C, 76.33; H, 11.12].

Jones oxidation of V produced the ketone VIa [54%; mp 40.5–42.0°;  $[\alpha]^{20}_D$  -39.8° ( $c$  0.8, CHCl<sub>3</sub>); infrared (neat): 3.30 (probably cyclopropyl H, w), 5.92  $\mu$  (C=O, s); pmr (CDCl<sub>3</sub>): three-proton singlet at  $\delta$  3.47 (methoxyl), 1.12 (angular Me), six-proton pair of doublets at 0.83, 0.81 ( $J$  = 5.5 cps, isopropyl methyls). *Anal.* Found: C, 76.96; H, 10.21] whose

(4) J. A. Marshall, W. I. Fanta, and G. L. Bundy, *Tetrahedron Letters*, 4807 (1965), have executed a synthesis of *d*-valeranone along traditional lines.

(5) G. F. Hennion and F. P. Kupiecki, *J. Org. Chem.*, 18, 1601 (1953).

(6) While neither this vinyl ketone nor the keto diether appears to have found use in Robinson annelation reactions heretofore, the condensation of 2-methyl-3-hydroxy-2-cyclohexenone with a mixture of 3-methoxy-4-diethylamino-2-butanone and 1-methoxy-4-diethylamino-2-butanone (also an *in situ* precursor of methoxymethyl vinyl ketone), derived from a Mannich condensation of methoxyacetone, formaldehyde, and diethylamine, is on record [J. Szmuszkovicz, *ibid.*, 19, 1424 (1954)].

(7) Even though the Robinson ring annelation reaction is nowadays part of the standard repertoire of organochemical synthesis, the choice of the all-important vinyl ketone component in the Michael condensation is limited usually to compounds with no more daring structural variation than different alkyl substituents. The recent utilization of carbomethoxymethyl vinyl ketone in an annelation process was of immense value in diterpene synthesis [E. Wenkert, A. Afonso, J. B. Bredenberg, C. Kaneko, and A. Tahara, *J. Am. Chem. Soc.*, 86, 2038 (1964)]. Methoxymethyl vinyl ketone or its equivalents can be expected to assume similar importance in the future.

## Biosynthesis of Mesembrine. The Incorporation of One-Carbon Units and the Origin of the C<sub>6</sub> Unit<sup>1</sup>

Sir:

The alkaloid mesembrine (1, R = R' = O) along with several congeners, mesembrinol (1, R = OH; R' = H) and mesembrinine (2), occur in several plants of the *Aizoacea* family.<sup>2</sup> The biosynthesis of these alkaloids is of interest since the skeletal framework would appear to contain a C<sub>6</sub>-C<sub>2</sub>-N unit, which in the case of mesembrine is comprised of the cyclohexanone ring and the attached C<sub>2</sub>-N bridge, and a C<sub>6</sub> unit represented by the aromatic ring. The presence of an isolated C<sub>6</sub> unit is an unusual structural feature, and its biosynthetic origin is therefore of interest. We report the results obtained which provide information on a precursor to this unit and also the results obtained from the incorporation of the label from methionine-S-methyl-C<sup>14</sup> into mesembrine.

The labeled compounds were fed to *Sceletium strictum* L. Bol.,<sup>3</sup> and after periods ranging from 3 to 22 days the plants were harvested and the mesembrine isolated by using inactive mesembrine as a carrier. The results are summarized in Table I and are for mesembrine of constant activity. When the mesembrine derived

from the methionine feeding experiment was demethylated to give the activities for the O-methyl and N-methyl groups separately, the total activity was, within the limits of experimental error, the same as in

Table I. Incorporation of Radioactive Compounds into Mesembrine<sup>a</sup>

Precursor	In- jected, μcuries	Iso- lation, days	Incor- poration, % <sup>b</sup>
Methionine S-methyl-C <sup>14</sup>	50	3	0.75
Tyrosine-3-C <sup>14</sup>	50	10	0.051
Phenylalanine-2-C <sup>14</sup>	50	10	<0.001
Phenylalanine [uniformly labeled in the ring with C <sup>14</sup> ]	50	22	0.059
	50	10	0.053

<sup>a</sup> Samples were counted on a Nuclear Chicago Unilux scintillation counter in toluene or dioxane-methanol-water scintillator solutions. <sup>b</sup> This figure may be regarded as a minimum since it was calculated on the basis of the weight of inactive mesembrine added to the plant extract.

the alkaloid. Furthermore, the ratio of the activities for the two methoxyls and the N-methyl group was 2:1. This suggests that each of these one-carbon sites makes an equal contribution to the total activity, in accordance with expectation for the result of a transmethylation process involving the S-methyl group of methionine.<sup>4</sup>

These results were independently confirmed by the degradation of radioactive mesembrine to veratric acid and demethylation of the latter to protocatechuic acid. The relative activities of the products of the degradation sequence are shown in Table II.

Radioactive mesembrine derived from phenylalanine [C<sup>14</sup>-ring labeled] was converted to veratric acid which was degraded further to protocatechuic acid. The relative activities of the degradation products indicate that the aromatic ring of phenylalanine is incorporated intact into the aromatic ring of mesembrine and that the label is restricted to this portion of the molecule. These results, when considered in conjunction with the results of the incorporation of radioactivity from tyrosine-3-C<sup>14</sup> and the lack of activity in the mesem-

**Table II.** Relative Activities of Mesembrine and Its Degradation Products

	Methionine-S-methyl-C <sup>14</sup>	Phenylalanine (C <sup>14</sup> -ring labeled)
Mesembrine	1.00	1.00
Veratric acid	0.64	1.00
Protocatechuic acid	<0.01	1.01
Methoxyls <sup>a</sup>	0.58	...
	0.64 <sup>b</sup>	...
N-Methyl <sup>a</sup>	0.36	...

<sup>a</sup> The activity on the carbons of the methoxyls and the N-methyl group in mesembrine was determined by the Zeisel method in which the liberated methyl iodide was trapped as (CH<sub>3</sub>)<sub>4</sub>NI and converted to the chloride on Dowex AG 1-X8 before counting.

<sup>b</sup> Figure obtained from demethylation of veratric acid.

brine derived from phenylalanine-2-C<sup>14</sup>, indicate (1) that phenylalanine is not converted to tyrosine before incorporation into mesembrine, (2) phenylalanine can serve as the precursor of the aromatic C<sub>6</sub> unit of the alkaloid, and (3) further suggest but do not prove that

tyrosine may serve as a precursor of the C<sub>6</sub>-C<sub>2</sub>-N unit.<sup>1</sup>

The results on the incorporation of these precursors into mesembrine are reminiscent of those obtained for the *Amarylolidaceae* alkaloids of the structurally related crinine series; cf. haemanthamine (3).<sup>8</sup> Experiments to test the possibility that mesembrine is biosynthesized by a route which may be considered as an extension of that known to occur<sup>7</sup> in the crinine series are in hand.

(5) Degradation studies designed to determine the position of the label in the mesembrine derived from tyrosine-3-C<sup>14</sup> which would establish this are in progress.

## Book Reviews

**Electrophilic Additions to Unsaturated Systems.** By P. B. D. DE LA MARE, M.Sc. (New Zealand), D.Sc. (London), F.R.I.C. Professor of Chemistry, Bedford College, University of London, Regent's Park, London N.W.1, and R. BOLTON, B.Sc. (W. Australia), Ph.D. (Hull), Lecturer in Chemistry, Bedford College, University of London, Regent's Park, London, N.W.1. American Elsevier Publishing Co., 52 Vanderbilt Ave., New York, N. Y. 1966. x + 284 pp. 14.5 × 21.5 cm. \$14.50.

There is a tremendous amount of useful information in this relatively small book, which is primarily concerned with acid-catalyzed additions to olefinic double bonds. The additions of electrophilic hydrogen (water, weak and strong acids), halogens, oxygen, sulfur, nitrogen, phosphorus, arsenic, and the elements of groups I-IV are covered in Chapters 3-10. In the last three chapters one finds a treatment of electrophilic additions to acetylenes and allenes (Chapter 11), conjugated double bonds and aromatic hydrocarbons (Chapter 12), multiple bonds between carbon and other atoms, and also the N=N and S=O double bonds (Chapter 13). The text is well written in a clear, uncomplicated manner. Although there is too much material covered to expect all of it to be presented critically, the authors do a good job of analyzing the validity of the results they review.

Books which contain discussions of so many isolated experiments often lack continuity, but Drs. de la Mare and Bolton somehow manage to avoid that pitfall. The only criticism I have to make is that Chapter 2, titled "The Chemistry of Carbonium Ions" (despite the claim on the dust jacket that it is an important chapter), could better have been omitted, for it is an attempt in 19 pages to review all other carbonium ion processes not included in electrophilic additions to unsaturated molecules. Such material has been so well covered elsewhere that it is unnecessary here, and, further, it cannot be adequately treated in so brief a manner.

The authors, however, have provided a gold mine of information for professors who give graduate courses in physical organic chem-

istry, because their effort has produced a competent and critical survey of a field which has not previously been well reviewed. This last fact alone is enough to make "Electrophilic Additions to Unsaturated Systems" a popular monograph, for it fills a glaring gap in the literature of carbonium ions.

Although the subject matter is probably too specialized to be of much use to the average undergraduate, most practicing organic chemists can profit by reading this book.

**The Peptides. Volume II. Synthesis, Occurrence, and Action of Biologically Active Polypeptides.** By EBERHARD SCHRÖDER and KLAUS LÜBKE, Hauptlaboratorium der Schering AG, West Berlin, Germany. Translated by ERHARD GROSS, National Institutes of Health, Bethesda, Maryland. Academic Press Inc., 111 Fifth Ave., New York, N. Y. 1966. xxvii + 632 pp. 16 × 23 cm. \$30.00.

This admirable book is a thorough, well-written compilation of information on biologically active peptides as it existed at the end of 1964. Together with the companion volume on synthesis, it will undoubtedly become the standard reference on peptides.

In common with most books designed to give a large amount of information in concise form, this book will not be exciting reading—

at least to the nonexpert. Its presentation is well organized, direct, and clear. The translation from the original German by Dr. E. Gross is excellent, and typographical errors are almost nonexistent.

The authors indicate in the Introduction that the book is written for the peptide chemist. Therefore, a critical comparison of different syntheses for a naturally occurring peptide could be expected, and indeed could be the most valuable contribution. Although some criticism is made, it is not enough. Take the example of oxytocin. The synthesis of this hormone by du Vigneaud and associates in 1953 is generally regarded as the first milestone in modern peptide synthesis. The importance of this synthesis is mentioned only in the Introduction. Reading on to the synthesis of oxytocin by Boissonnas and associates, we find a statement that their approach is more rational, but no reason is given why. Then, further on, the stepwise *p*-nitrophenyl ester synthesis by Bodanszky and du Vigneaud is given without any indication of its importance as the first significant synthesis by the now very popular active-ester approach.

There are many other places where the authors, who are well qualified by their own important contributions, could have given valuable critical appraisal as to the possibility of racemization, superiority of one synthesis over another in yields, etc. Generally speaking, the peptide chemist must still go back to the original literature for these comparisons, but Schröder and Lübke have given him a fine starting point.

This book will be useful to anyone interested in structure-activity relationships of peptides. Excellent tables for comparison are given; for instance, the table for oxytocin derivatives and analogs summarizes testing results on 67 compounds. The authors, of course, could only give results as reported in the literature, and, since biological testing results vary from one laboratory to another, absolute comparisons are not possible.

Since the peptide field is a broad one, including hormones, pressor and depressor substances, antibiotics, and even enzymes by an extension of the definition, it is unquestionably important. A few synthetic peptides are becoming available as drugs (oxytocin, angiotensin, ACTH derivatives), and undoubtedly there will be more. The work reported by Schröder and Lübke was mostly done in the past ten years, a testimony to improved methodology and increased interest. The next few years should bring even greater advances.

**Molecular Biology of Human Proteins with Special Reference to Plasma Proteins. Volume 1. Nature and Metabolism of Extracellular Proteins.** By H. E. SCHULTZE, Formerly Scientific Director of the Behringwerke AG, Marburg/Lahn, Germany, and J. F. HEREMANS, Professor of Internal Medicine, University of Louvain, Belgium. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 1966. xii + 904 pp. 18 × 25 cm. \$52.50.

The first of two volumes on "Molecular Biology of Human Proteins" is a veritable encyclopedia. It is extremely heavily documented, having over 5500 references, and will serve as an excellent starting point for becoming familiar with almost any aspect of the subject. A unique feature is a comprehensive large chart relating the sedimentation coefficients of the various serum proteins with their behavior on paper and starch gel electrophoresis and on immunoelectrophoresis, followed by a table listing 93 different proteins found in serum and 43 tables giving additional data on those which have been obtained in purified form. A general introduction to structure and molecular and genetic variation in proteins is followed by sections on analytical methods in protein chemistry, the data on the various serum proteins mentioned above, methods of fractionation, synthesis and turnover of plasma proteins, and exchange between mother and child. The final section contains 10 chapters on proteins of extravascular fluids including intestinal fluids, urine, cerebrospinal fluid, saliva, milk, and colostrum, etc.

Both authors have had extensive experience in working with serum proteins, and one finds useful critical comments in their presentation of the subject matter. As with all encyclopedic works it tends to be sketchy in some areas; for example, it is doubtful that

one can learn much about the principle of electron spin resonance from the little more than a page devoted to it without consulting the references. A most objectionable feature is not the fault of the authors but of the publisher who used a very glossy paper so that one is constantly disturbed by reflection and glare while reading by artificial light. All in all the book is of great value and should be widely consulted.

Elvin A. Kabat

The gratifying response from academic institutions and research institutes to our Rayonet RPR-100 photochemical reactor made us realize that there is a strong need for photochemical equipment designed specifically for research in photochemistry. For the synthetic organic chemist who is interested in reactions on a mole scale we now offer the new Rayonet® RPR-208 type RS Preparative Reactor which we feel is the most versatile equipment for photochemical experiments in the region from 200 to 450 mμ.

\*TRADEMARK

## Methods In Preparative Organic Photochemistry No. 1

# Chemical Yields and Quantum Yields

A synthetic organic chemist may choose to ignore the quantum yield and concentrate his attention on the chemical yield which after all spells out the utility of a photochemical reaction. But the unfortunate fact about most photochemical reactions is that the time it takes to direct enough photons into the reaction vessel usually introduces another factor which cannot be ignored. The duration of a photochemical reaction is invariably measured in hours, frequently in days. This time is costly if the research worker has to watch the irradiation equipment constantly. It is no longer possible to leave a sealed ampoule of the material on the roof of the laboratory for six months in the hope that sunlight which is both cheap and plentiful (in certain latitudes) will make the reaction go.

The photoisomerization of 1, 3-dienes is a useful synthetic method for the preparation of the relatively rare cyclobutenes.<sup>1</sup>

The chemical conversion in the reaction is essentially 100 per cent if a very dilute solution

(1-3 per cent) of the diene is used. The one exception among the simple dienes is 1, 3-butadiene which gives about 85 per cent of cyclobutene and 15 per cent of bicyclobutane.<sup>2</sup> But these isomerizations have very low quantum yields which range from 0.1 to 0.01. To convert 2 moles of 1, 3-butadiene would require 200 einsteins of photons of the right wavelength. The RPR-208 reactor gives 120 watts of uv light at 254 mμ which is highly suitable for irradiating 1, 3-dienes including 1, 3-butadiene. Yet its power input is only 500 watts. It requires no external cooling nor any special high-voltage power supplies so that it needs virtually no attention while in operation.

It is more practical to use somewhat more concentrated solutions of the diene (10-15 per cent) in an inert solvent with a b.p. at least 40° different. The solution is taken in a cylindrical quartz vessel and irradiated for a few days until all of the diene is consumed. To isolate the product it is merely necessary to separate the solvent and any polymeric residue by distillation. In the case of cyclobutene, the bicyclobutane can be readily eliminated by letting the material stand over powdered maleic anhydride.

# Problems in Spectroscopy

Organic Structure  
Determination  
by NMR,  
IR, UV, and Mass Spectra

**Barry M. Trost**

University of Wisconsin

412 Pages Paperbound, approx. \$2.95  
Clothbound, approx. \$7.00

This series of problems in spectroscopic methods of structure determination is intended to supplement senior-graduate courses on spectroscopy in organic chemistry and to reacquaint research chemists with its methods. After the problems have been done, it will serve as an excellent reference of standard spectra in which all the spectral data for a single compound are in one place.

Over 200 sets of problems are included, involving almost all the major classes of organic compounds. Each problem consists of a reproduction of the IR, UV, NMR, and in most cases, mass spectra. Compounds possessing typical IR functional group absorptions, UV chromophores, NMR splitting patterns, and MS fragmentation patterns are included. In addition, an information card appears with each unknown which contains data such as the compound number, molecular weight, an analysis for the elements, and any deviation from the standard set of recording conditions used.

## *Interscience announces the* **INTERNATIONAL JOURNAL OF QUANTUM CHEMIST**

*Editor-in-Chief* PER-OLOV LÖWDIN, *Univ  
of Uppsala, Sweden, and University of Fl*

This new journal is devoted to original paper quantum mechanics and its applications to theory of atoms, molecules, and crystals. Particular attention is given to the following fields: Fundamental concepts and mathematical structure quantum chemistry; Applications to atoms; Applications to molecules; Applications to crystal; Applications to molecular biology; and Computational methods of quantum chemistry.

This journal consists of two parts: regular monthly issues, and symposia (issued irregularly). The first of the symposia, scheduled for publication in 1967, will comprise the proceedings of the International Symposium in Atomic, Molecular, and Solid-State Theory in Honor of Professor J. Slater, held in Florida in January, 1967. Manuscripts received for the regular issues and symposia indicate that subscribers will receive at least 12 pages of material.

*1967 subscription rate: \$70.00*

### Business and Subscription Information

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the Subscription Service Department, American Chemical Society, 1155 Sixteenth Street, N.W., Washington, D. C. 20036. Change of address notification should include both old and new addresses, with ZIP codes, and a mailing label from a recent issue. Allow four weeks for changes of address.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue plus time normally required for postal delivery of journal and claim, (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Subscription rates for 1967: to members, \$16.00 per year, to nonmembers, \$32.00 per year. Postage to Canada and countries in the Pan-American Union, \$2.50; all other countries, \$3.50. Back volumes: Vol. 36-88, \$48.00 per volume; foreign postage, per volume, \$3.50; to Canada and countries in the Pan-American Union, \$2.50.

Single copies: back issues, \$2.50; for current year, \$2.00; postage, single copies: foreign, \$0.20; Canada and Pan-American Union, \$0.15.

## This is a corporation talking.

As an artificial person, we can  
aspire to immortality.

Makes a convenient façade  
for lively mortals.

If we hadn't had good people we wouldn't be where we are today, but we don't have enough of them to face the problems of the years ahead.

We are getting smarter. We now understand that just people aren't enough. We require *individuals*—no two too much alike.

Ideally, we hope by these words to attract into our midst an individual who will proceed to scientific accomplishments that freshman textbooks of the 1990s can scarcely ignore. An alternative ideal outcome would be to attract another and very different individual who will eventually turn from direct personal contribution to science and will wind up as chairman of the corporation's board of directors in the 1990s.

The effort will still have been worthwhile if it merely advises a few scientists that our size, organic integration, and diversification mean for the individual a freedom of choice where his scientific interests and experiences can lead him as the years go on. We serve human needs both through the photographic process and through technologies now grown far away from photography. Thus we find economic support for a very broad range of fundamental studies on which the technologies may possibly feed. Hence the freedom in area of work.

We have come to appreciate also the need for freedom in choosing the direction of approach to scientific problems. Strongly motivated scientists we can set free to put up to 100% of their working time into research. They can have assistance and auxiliary laboratory services by colleagues themselves well recognized as experts in their techniques—a situation that fortunately prevails

in the Kodak Research Laboratories. They can communicate freely with peers and yet need not carry the "teamwork" figure of speech to where one forgets his own name in return for a dry stall and an assured bag of oats.

## Physical and Inorganic Chemistry

### Solute-Solvent Interactions. I. Evaluations of Relative Activities of Reference Cations in Acetonitrile and Water

J. F. Coetzee<sup>1</sup> and J. J. Campion<sup>2</sup>

Contribution from the Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15213. Received December 12, 1966

**Abstract:** Extrathermodynamic methods that have been used to split solvation energies of electrolytes into the ionic components and to compare single ion activities in different solvents are reviewed critically. In this work, the application of the Born equation is restricted in such a manner that the probable reliability of the comparisons is improved significantly. The free energy of transfer from acetonitrile to water associated with potentially useful reference couples, including the rubidium, thallium, ferrocene, and ferroin systems, is evaluated. The relative advantages of these couples are discussed.

It is well known that the properties of electrolytic solutes quite generally are modified substantially by interaction with the solvent. However, quantitative information about this important process is limited. In order to assess the relative extent of such interactions in various solvents, it is necessary to estimate single ion activities in different solvents relative to a common standard state.

The basic problem of evaluating single ion activities and Galvani potentials, and the related ones of comparing potentials in different solvents and splitting the solvation energies of electrolytes into the ionic components, constitute classical dilemmas of chemistry which have received much attention.<sup>3-5</sup> The essential point is that, since the problem is not accessible to exact thermodynamics, it is necessary to follow extrathermodynamic procedures. Perhaps the most promising approach at present is based on an assumed ideal (nonspecific) behavior of certain solutes with respect to their oxidation-reduction or their solubility properties. Thus various authors have assumed that the standard

potentials of couples such as rubidium ion-rubidium amalgam,<sup>6,7</sup> ferricinium ion-ferrocene,<sup>8</sup> or the iron-(III-II) complexes of the phenanthrolines<sup>9,10</sup> are relatively insensitive to specific solvation effects and therefore should be reasonably constant in different solvents. In a related approach, Popovych<sup>11</sup> has estimated single ion solvation energies from solubility data by assuming that in any given solvent the cation and anion of an appropriate reference electrolyte, such as triisoamylbutylammonium tetraphenylboride, will have equal free energies of solvation. These assumptions all suffer from certain limitations. Thus, the assumed equality of the free energy of solvation of the ions of the above reference electrolyte is based on the transport properties of the ions, specifically the approximate equality of the Stokes radii in methanol and water.<sup>12</sup> However, no simple correlation necessarily exists between the transport properties and the free energy of solvation of an

ion, because other factors also affect transport properties. One such factor is the additional frictional force produced as a result of the dielectric relaxation induced by ionic motion in a polar medium;<sup>13</sup> another is the change in local viscosity produced by the structure-making and structure-breaking properties of ions in a solvent such as water;<sup>14</sup> and, finally, the size and effective "number" of the solvent molecules accompanying the ion during its migration also enter into its transport properties. This problem would persist even if a more ideal reference electrolyte, such as tetraisoamylammonium tetraisoamylboride,<sup>15</sup> were used. The uncertainty would be particularly large in a dipolar aprotic solvent, such as acetonitrile, which solvates anions (except those that are highly polarizable) much more poorly than cations. For such solvents, splitting solvation energies of electrolytes on any basis involving directly or even indirectly the properties of an anion probably should be avoided. Furthermore, reference electrolytes of the type under discussion have quite high solubilities in dipolar aprotic solvents, and the required activity coefficients for the saturated solutions may be difficult to measure. Nevertheless, Popovych's approach may be eminently suitable for comparisons among solvents of similar relative solvating power for cations and anions, such as the water-methanol pair actually studied.<sup>11</sup>

As far as the use of reference redox couples for the comparison of potentials in different solvents is concerned, desiderata include the lowest and most shielded charge possible, maximum size and symmetry, and minimum polarizability. Other factors to be considered are listed in ref 8. The high-charge type of the iron(III-II)-phenanthroline couples presents a serious problem; the Born equation (see below) predicts that for equal effective radii the free-energy difference associated with a III-II couple will be five times as large as that for a I-0 couple. This problem persists even after due allowance has been made for the effect of ionic strength on the formal potentials in both solvents (through activity coefficients and possible incomplete electrolytic dissociation). Furthermore, specific solvation effects generally are magnified with ions of high-charge type.

For the reasons mentioned above, we prefer to base our comparisons on I-0 couples, such as the rubidium (or cesium) and the ferrocene systems. The latter has the important advantage of considerably greater size, but a serious uncertainty comes from the fact that the reduced form of the couple is also present in solution, so that its solvation energy is involved, and this may vary considerably from one solvent to another (see below). For this reason we place prime emphasis on the rubidium scale, adjusted by a suitable modification of the Born equation, as described in this paper. The thallium(I-0) potential is then placed on this scale, and from the solubilities of thallium(I) salts the relative activities of anions in acetonitrile and water are evaluated, as described in the next paper.

## Experimental Section

**Preparation and Purification of Chemicals.** Matheson Coleman and Bell practical grade acetonitrile was purified as described

before.<sup>16</sup> Thallium(I) perchlorate was prepared by treating 10 g of Fisher Purified thallium(I) nitrate with 40 ml of 3 M perchloric acid, evaporating to dryness, and then recrystallizing three times from water and drying at 120°. Tetraethylammonium perchlorate was prepared as described elsewhere.<sup>17</sup> Thallium amalgam was prepared by adding Fisher Purified thallium metal to Bethlehem Apparatus Co. triple-distilled mercury and heating with an infrared lamp under a nitrogen atmosphere. Analysis of the amalgam by acidimetric titration<sup>18</sup> showed that it contained 0.74 mole % of thallium. It was stored under 0.01 M aqueous sulfuric acid.

**Potentiometric Experiments.** Measurements were made with a Leeds and Northrup Model 8687 precision potentiometer. An H-type cell was constructed with 10-mm diameter fritted glass disks of fine porosity inserted 5 cm apart in the horizontal (salt bridge) section of the cell. Between the two disks a vertical tube was provided for the introduction or removal of salt bridge solution. In all experiments, one working (vertical) compartment of the all-acetonitrile cell contained an Ag(0.01 M AgNO<sub>3</sub>) electrode as reference.<sup>19</sup> The salt bridge compartment contained 0.1 M tetraethylammonium perchlorate. In the measuring compartment a thallium amalgam electrode dipped into deaerated 0.01 M tetraethylammonium perchlorate containing varying amounts of thallium(I) perchlorate. Immediately before use the thallium amalgam was washed twice with deionized water and then twice with acetonitrile, after which it was introduced into a J-tube electrode.<sup>20</sup> An atmosphere of nitrogen saturated with acetonitrile was maintained during all measurements.

## Results and Discussion

In Table I the crystallographic radii and polarographic half-wave potentials of the alkali metals in acetonitrile and water are compared.<sup>7,21,22</sup> In Table II the standard reduction potentials of various couples in the same solvents are compared.<sup>8,10,23-25</sup>

**Standard Potential of Thallium.** From the results of three different series of experiments with 0.74 mole % thallium amalgam in the following cell

plots of emf *vs.* log *C* were linear with slopes near the theoretical value of 59 mv for values of *C* in the range 10<sup>-3</sup> to 10<sup>-4</sup> M. Extrapolation to *C* = 0 gave a formal potential (on the molar scale) *E*<sub>0</sub>' for the particular amalgam used in 10<sup>-3</sup> M Et<sub>4</sub>NClO<sub>4</sub> of -0.521 ± 0.003 v *vs.* the Pleskov reference electrode, hereafter designated as PE.

The Debye-Hückel equation for the rational activity coefficient, *f*<sub>±</sub>, of a 1:1 electrolyte in acetonitrile is

$$-\log f_{\pm} = \frac{1.64S^{1/2}}{1 + (0.485aS^{1/2})} \quad (1)$$

where *S* represents the ionic strength. Rational and molal activity coefficients in acetonitrile are related as follows through the molality, *m*, of the electrolyte and the molecular weight, *M*, of acetonitrile.

$$\gamma_{\pm} = f_{\pm}/(1 + 2 \times 10^{-3} \text{ mM}) = f_{\pm}/(1 + 0.082 \text{ m}) \quad (2)$$

It is evident that at molalities below 0.1 the two scales

<sup>a</sup> Computed from amalgam potential given in ref 19; see text. <sup>b</sup> This work. <sup>c</sup> Reference 10; also see ref 8 and 35. <sup>d</sup> Born correction of +0.149 applied to value for water. On this basis the Ag|0.01 M AgNO<sub>3</sub> (AN) reference electrode has a potential of +0.503 v referred to nhe (W); see text. <sup>e</sup> Reference 23. <sup>f</sup> Reference 24.

differ by less than 1%. Salts such as Et<sub>4</sub>NClO<sub>4</sub>, which contain relatively "ideal" ions, are completely dissociated in acetonitrile at concentrations which are as low as 10<sup>-3</sup> M;<sup>16</sup> hence  $S \sim 10^{-2}$ . Assuming that the ion-size parameter  $a$  can be approximated by the Stokes radii<sup>18</sup> for Et<sub>4</sub>N<sup>+</sup> (2.79 Å) and ClO<sub>4</sub><sup>-</sup> (2.29 Å), it is found that  $a \sim 5$  Å and hence  $\gamma_{\pm} \sim f_{\pm} = 0.74$ . The formal potential,  $E_0'$ , is related to the standard (reduction) potential,  $E_0$ , as

$$E_0' = E_0 + 0.059 \log f_{Tl} / (f_x)_{Tl(Hg)} \quad (3)$$

where  $x$  is the mole fraction of thallium in the amalgam. Assuming that for the very dilute amalgam used  $f_{Tl(Hg)} = 1$ , it is found that  $E_0 = -0.639$  v *vs.* PE. Applying the small correction of -0.0025 v for the free energy of amalgamation of thallium,<sup>28</sup> a final value of  $E_0 = -0.642$  v *vs.* PE is obtained. Since the density of acetonitrile is equal to 0.777 g ml<sup>-1</sup>, the corresponding value of  $E_0$  on the molal scale is  $-0.642 - 0.006$  or  $-0.648$  v *vs.* PE.

**Standard Potential of Rubidium.** Pleskov<sup>19</sup> measured an emf of 2.3275 v for the following all-acetonitrile cell with 0.54 mole % amalgam.

The Stokes radii of Rb<sup>+</sup> and I<sup>-</sup> are 2.75 and 2.33 Å, respectively. Hence, assuming a value of 5 Å for the ion-size parameter for RbI, we calculated from eq 1 that  $f_{\pm} = 0.74$ . Lewis and Argo<sup>23</sup> determined the free energy of amalgamation of Rb by measurements on the following cell: Rb(Hg)|RbI in EtNH<sub>3</sub> containing 7.9 mole % NH<sub>3</sub>/Rb. With 0.54 mole % amalgam (the same concentration as that used later by Pleskov), the emf was 1.0745 v. Consequently the standard potential of Rb in acetonitrile (on the molal scale) is given by

$$E_0 = -2.3275 - 0.059 \log (0.74 \times 10^{-3}) -$$

$$1.0745 - 0.006 = -3.282 \text{ v } \textit{vs.} \text{ PE}$$

**Rubidium Potential Referred to the Water Scale. Modification of the Born Equation.** The main purpose of this paper is to refer the potentials measured in acetonitrile *vs.* PE (listed in the second column of Table II) to that of the normal hydrogen electrode in water. Our reasons for selecting the rubidium potential for this purpose have been given in the introductory section.

The change in *electrostatic* free energy occurring when a mole of electrolyte is transferred from the gas phase to a medium of dielectric constant  $D$  is given as a first approximation by the Born equation

$$\Delta G_{\pm}^{\circ} = -\frac{N\epsilon^2}{2} \left( 1 - \frac{1}{D} \right) \left( \frac{z_+^2}{r_+} + \frac{z_-^2}{r_-} \right) \quad (4)$$

where  $r_+$  and  $r_-$  are the crystallographic radii of the cation and anion, respectively, and other symbols have their customary meaning. However, it is well known that the Born equation has the serious limitations that it recognizes neither specific solvation nor dielectric saturation. For the relatively ideal solutes considered here, specific solvation effects are likely to be unimportant, but the same is not true of the differences in dielectric saturation that may be expected in water and acetonitrile. There is no consensus about the quantitative aspects of dielectric saturation in water,<sup>26</sup> although a modification of the Born equation which explicitly allows for this perturbation has been used with apparent success to calculate free energies of transfer from water to deuterium oxide<sup>27</sup> and to water-alcohol mixtures.<sup>28</sup> Too little is known about dielectric saturation in acetonitrile to allow a quantitative treatment here. However, from a rough comparison of the known polarizability of the C≡N bond in HCN (31 Å<sup>3</sup>)<sup>29</sup> and the average polarizability of the water molecule (14 Å<sup>3</sup>),<sup>30</sup> it can be predicted qualitatively that dielectric saturation may be even more pronounced in acetonitrile than in water. (The dipole moments of acetonitrile and water are 3.37 and 1.84 D., respectively.)

In the absence of a reliable estimate of the effective dielectric constants of water and acetonitrile, the only practical approach is the well-known one introduced by Latimer, Pitzer, and Slanski,<sup>31</sup> in which the effective

radii of the solute ions, rather than the dielectric constant of the solvent, are corrected.

$$\Delta G_{\pm}^{\circ} = -\frac{N\epsilon^2}{2} \left(1 - \frac{1}{D}\right) \left(\frac{1}{r_{+} + r_{+}'} + \frac{1}{r_{-} + r_{-}'}\right) \quad (5)$$

A single pair of values for the correction terms  $r_{+}'$  and  $r_{-}'$  gives a fairly self-consistent match of calculated and experimental solvation energies for the alkali metal halides in water. This self-consistency provides some justification for the use of eq 5 to split solvation energies into the ionic components. Strehlow and his co-workers<sup>8</sup> have carried out such a split for acetonitrile by comparing the solubilities ( $S$ ) of the alkali metal halides in water (W) and acetonitrile (AN)

$$\Delta G_{\pm}^{\circ} \text{AN} = \Delta G_{\pm}^{\circ} \text{W} + 2RT \ln \frac{S_{\text{W}}}{S_{\text{AN}}} \quad (6)$$

and then fitting the  $\Delta G_{\pm}^{\circ} \text{AN}$  values to eq 5. Omitting activity coefficients (which are unknown), the results lead to average correction terms  $r_{+}'$  and  $r_{-}'$  of 0.72 and 0.61 Å for acetonitrile, as compared to Latimer, Pitzer, and Slanski's values (subsequently revised; see below) of 0.85 and 0.25 Å, respectively, for water. However, the fluctuations in these values for the individual salts in acetonitrile are quite large. Furthermore, the smaller value of  $r_{+}'$  in acetonitrile means that the alkali metal ions are more strongly solvated in that solvent than in water, which is the opposite of what polarographic and other data unambiguously show to be the case. For example, the second last column of Table I shows that the half-wave potentials of the smaller alkali metal ions referred to that of rubidium or cesium are more negative (corresponding to more difficult reduction of the ion) in water than in acetonitrile, and that this negative shift increases smoothly with decreasing size of the ion. It is clear that all of these ions must be more strongly solvated in water than in acetonitrile. The stronger solvation of cations by water, as compared to that by acetonitrile, is not restricted to the alkali metals. In particular, high-charge type ions [e.g., Eu(III)] show large positive shifts in half-wave potential in acetonitrile,<sup>7</sup> and spectrophotometric and a host of other data show that the proton is solvated much more strongly by water than by acetonitrile.<sup>32</sup>

We now assume that the Born equation can be modified empirically according to the approach of Latimer, Pitzer, and Slanski to account for this negative shift in water. This is done with due cognizance of the demonstrated limitations of the Born equation in predicting absolute values of the electrostatic free energy of transfer of ions from the gas phase to water. However, by restricting the use of the equation to the difference between water and acetonitrile, and by imposing *still another restriction* by comparing this difference for rubidium with those for the other ions, many of the uncertainties inherent in the Born treatment should be eliminated. We assume that the "neutral" part of the solvation energy differences is the same in both solvents (zero-energy assumption<sup>21</sup>).

**Sample Calculation.** The second to last column in Table I shows that the difference between the half-wave potentials of lithium and cesium ions is 0.26 v smaller

in acetonitrile than in water, corresponding to a difference in solvation energy which is  $0.26(96,500 \times 10^{-3})/4.18$  or 6.0 kcal mole<sup>-1</sup> smaller in the former solvent. From Noyes' recent tabulation,<sup>21</sup> the average value of  $r_{+}'$  for water is  $0.72 \pm 0.03$ . Equation 5 with  $D = 78.5$  then predicts a difference in solvation energy of lithium and cesium of 56.1 kcal mole<sup>-1</sup> in water. Hence, in acetonitrile this difference amounts to  $56.1 - 6.0 = 50.1$  kcal mole<sup>-1</sup>. On substituting this value, and  $D = 36.0$ , for acetonitrile into eq 5, it follows that

$$50.1 = 161 \left( \frac{1}{0.60 + r_{+}'} - \frac{1}{1.69 + r_{+}'} \right)$$

from which the value of  $r_{+}'$  for acetonitrile is found to be 0.81 Å. Similar calculations for the pairs Li<sup>+</sup>-K<sup>+</sup> and Na<sup>+</sup>-K<sup>+</sup> (for which the differences in solvation energy are reasonably large) give  $r_{+}'$  values of 0.80 and 0.82 Å, respectively. We therefore assume an average value of 0.81, which on substitution into eq 5 leads to calculated positive shifts in the half-wave (or standard) potentials in acetonitrile as compared to water of 0.42, 0.28, 0.19, 0.17, and 0.15 v for Li, Na, K, Rb, and Cs, respectively. The last column of Table I shows an internally consistent agreement between calculated and observed differences in half-wave potentials. Virtually the same differences are calculated if the comparisons are based on the correction factor of Latimer, *et al.*, rather than that of Noyes. For exact comparisons of free-energy values in two different solvents it is necessary to allow for the difference in solvent molality in the two solvents. Such allowance is included in Gurney's  $J$  factors<sup>33</sup> and Frank and Rasaiah's "aquamolality" scales.<sup>34</sup> A correction of  $-0.021$  v is required for this purpose. Consequently the standard potential of rubidium becomes  $0.17 - 0.021 = 0.149$  v more positive in acetonitrile than in water. The standard potentials for the thallium, ferrocene, and ferroin couples in acetonitrile reported in the third column of Table II are based on this value.

In principle it should be preferable to apply the modified Born treatment to standard potentials, rather than half-wave potentials. However, the standard potential of lithium in water is uncertain<sup>24</sup> and that reported for lithium in acetonitrile<sup>19</sup> appears to be seriously in error. We have discussed elsewhere<sup>7</sup> factors to be considered in the comparison of half-wave potentials in different solvents. Many of the uncertainties associated with such comparisons should be minimized here, since only differences among the alkali metal ions are involved. For example, conductance data show that the influence of  $\text{M}^+\text{ClO}_4^-$  ion-pair formation should be similar for all alkali metal ions and is quite small.

**The Thallium, Ferrocene, and Ferroin Potentials.** The positive shift in the standard potential of the thallium(I-0) couple (0.191 v) is considerably larger than those for rubidium (0.149 v) or potassium (0.169 v), even though its crystallographic radius (1.40 Å) is intermediate between those of the two alkali metals (1.48 and 1.33 Å). We attribute this additional shift to the "abnormally" strong hydration of  $\text{Tl}^+$ ,<sup>21</sup> which may be the result of its empty 5f orbital.

the ferrocene potential is 0.18 v more positive in acetonitrile than in water. With  $r_+ = 3.8 \text{ \AA}$ <sup>35</sup> and values of 0.72 and 0.81 A for water and acetonitrile, respectively, eq 5 applied to ferricinium ion accounts for v of this positive shift. It may appear that the missing 0.12 v must be the result of a lower solvation energy of ferrocene in water than in acetonitrile. However, the actual ratio of the solubilities of ferrocene in water and acetonitrile is smaller than would be expected on this basis. Kolthoff and Thomas<sup>10</sup> determined a solubility value of  $1.7 \times 10^{-6} m$  voltametrically in aqueous 0.1 M Et<sub>4</sub>NClO<sub>4</sub> solution; we found a value of  $2 \times 10^{-6} m$  by extracting a saturated solution of ferrocene in pure water with carbon tetrachloride, evaporating (caution: ferrocene sublimes easily), and weighing. In acetonitrile we found a solubility of  $1.5 \times 10^{-6} m$ . Assuming that in both solvents the activity coefficient of ferrocene is near unity, the expected standard potential resulting from this cause would be near 0.24 v, rather than 0.12 v. It is possible that the decrease of 0.12 v in positive shift is caused by hydrophobic repulsion, which would decrease the activity of ferricinium ion in water. Finally, the observed solubility ratio of ferrocene in the two solvents corresponds to 18 eu, which may be attributed quite reasonably to the reduced entropy expected on the basis of the Frank-Evans model<sup>14</sup> as a result of possible formation of cage structures between ferrocene and ferricinium ion. We conclude that both ferrocene and ferricinium ion may be involved in specific interactions in water, and hence that this couple is unsuitable for purpose.

The ferroin potential is 0.23 v (or 0.20 v based on the value in ref 36) more positive in acetonitrile than in water. This shift corresponds to an average "effective"

) D. R. Stranks, *Discussions Faraday Soc.*, 29, 73 (1960).

radius term in the Born equation of ca. 2.5 A, a value which is uncertain but not unreasonable. Although the ligand molecules are large, the structure of the iron(III) and iron(II) complexes is quite open, permitting close approach of both water and acetonitrile molecules. An additional complication was reported by Kratochvil and Knoeck.<sup>36</sup> Partial molal entropy values for the ferroin couple in acetonitrile indicate, as expected, a greater degree of solvent ordering around the iron(III) than around the iron(II) complex, but in water the situation is reversed. This difference in solvent ordering was attributed to preferential hydrogen bonding of water to localized regions of electronegativity on the iron(II) complex. Clearly specific interactions occur.

It therefore appears that complexes such as ferrocene and ferroin, which contain large organic ligands, may be useful for comparisons among relatively similar nonaqueous solvents, but not for comparisons with water, which is involved in a variety of specific interactions with such ligands, the details of which at present are incompletely understood.

In conclusion, it is likely that application of the Born equation in the restricted manner described in this communication results in a significant improvement in the reliability of comparisons of potentials in water and acetonitrile. However, it should be stressed that unambiguous proof of the validity of any split of solvation energies in any solvent is impossible at present.

**Acknowledgments.** We are indebted to Professor Henry S. Frank of this department for stimulating discussions on the interaction of solutes with the structure of water. This work was supported by the National Science Foundation under Grant No. GP-1479.

## Solute-Solvent Interactions. II. Relative Activities of Anions in Acetonitrile and Water

J. F. Coetzee<sup>1</sup> and J. J. Campion<sup>1</sup>

*Contribution from the Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15213. Received December 12, 1966*

**Abstract:** The free energies of transfer of the halides and of nitrate, perchlorate, and picrate ions from water to acetonitrile have been evaluated. Striking differentiation in the activities of these ions occurs in acetonitrile, to such an extent as to justify the statement that the chemistry of electrolytes in this solvent generally is dominated by differences in the properties of anions. The implications of this statement are discussed.

Considerable circumstantial evidence indicates that in solvents which are dipolar but essentially aprotic, such as acetonitrile, acetone, nitromethane, N,N-dimethylformamide, and dimethyl sulfoxide, anions are solvated more weakly and therefore possess higher activities than is the case in water. Only two examples

will be given here. (a) Bimolecular reactions of anions which pass through large, polarizable transition states containing the anion proceed much more rapidly in aprotic solvents than in others. For example, the relative rates of the following S<sub>N</sub>2 reaction

in methanol, formamide, N-methylformamide, and N,N-dimethylformamide are 1, 12.5, 45.3, and 1.2

$\times 10^6$ , respectively.<sup>3</sup> Such striking differences in rates have many important implications in organic chemistry in particular; for details refer to the extensive discussions by Parker and co-workers.<sup>3,4</sup> (b) Many Brønsted acids dissociate in aprotic solvents, S, according to the following over-all scheme

in which the high activity of  $A^-$  results in "homoconjugation" (a term coined by Kolthoff) with the parent acid. Such reactions have been studied extensively in acetonitrile, particularly by Kolthoff and Chantooni,<sup>5</sup> and also by others.<sup>6</sup>

The chemistry of electrolytes in aprotic solvents generally differs markedly from that in other solvents. Many of the most striking differences are dominated by variations in the activities of anions, such as those described above. However, present knowledge about the quantitative aspects of these variations in activity is unsatisfactory. This communication is concerned with the evaluation of such effects.

It is important to improve our understanding of the chemistry of electrolytes in aprotic solvents, because in such solvents a clearer picture of the intrinsic properties of solutes can be obtained than is possible in a strongly masking solvent such as water. However, for various reasons water must remain a solvent of unique importance, and the complex spectrum of interactions occurring between water and solutes has far-reaching implications in many branches of science. It is evident that comparisons of solute properties in water and in "nonwaterlike" solvents are bound to clarify our understanding of interactions occurring with water.

In the first paper of this series,<sup>7</sup> we have presented the results of an extrathermodynamic evaluation of the free energy of transfer of certain reference cations, such as rubidium ion and also of thallium(I) ion, from water to acetonitrile. In the present paper the complementary quantities are evaluated for a series of anions from the relative solubilities of the corresponding thallium(I) salts in the two solvents. The results show striking differences in activity of anions in water and acetonitrile.

## Experimental Section

**Preparation and Purification of Chemicals.** Eastman White Label tetraethylammonium chloride and bromide were recrystallized from 2-propanol and dried *in vacuo* at 50°. Tetraethylammonium iodide was prepared by titrating Eastman Yellow Label tetraethylammonium hydroxide solution with Eastman 50% hydrogen iodide. The solution was concentrated by heating, and the crystals were filtered off and recrystallized from ethanol. The product was dissolved in a 1:1 mixture of ethanol and acetone, then precipitated with ether, and finally dried *in vacuo* at 50°. Tetraethylammonium thiocyanate was prepared directly in acetonitrile by treating a solution of tetraethylammonium chloride with a 1% excess of Baker Analyzed Reagent potassium thiocyanate and then filtering off potassium chloride, which is virtually insoluble in acetonitrile. The solution was standardized by titration with silver nitrate. Fisher Purified thallium(I) nitrate was recrystallized from water and dried at 120°. Other chemicals were treated as described.<sup>7</sup>

**Potentiometric Experiments.** The apparatus was the same as that described previously. Solubility products of the thallium(I) halides and thiocyanate were determined by measuring the potential of a thallium amalgam electrode in a solution prepared by adding  $5 \times 10^{-4}$  to  $5 \times 10^{-3}$  M thallium(I) perchlorate to  $5 \times 10^{-3}$  M tetraethylammonium halide or thiocyanate.

**Radioactivity Measurements.** All measurements were made with a Geiger counter coupled with a Nuclear Chicago decade scaler (Model 181). Samples were counted on stainless steel planchets mounted on aluminum cards and covered with Mylar. Radioactive thallium(I)-204 nitrate supplied by the Oak Ridge National Laboratory was diluted with water to give an activity of ca. 1 mcurie/ml, and this solution was then used to dissolve an accurately weighed 100-fold excess of inactive thallium(I) perchlorate and to make it up to exactly 10 ml, giving a 0.500 M labeled solution. Precipitates of labeled TlCl, TlBr, TlI, and TlSCN were prepared by treating exactly 1 ml of this labeled solution with exactly 1 ml of 0.525 M reagent quality NaCl, KBr, KI, and NaSCN, respectively. The precipitates were washed at least four times with distilled water, transferred to polypropylene bottles, and dried *in vacuo* at 60°. Acetonitrile was added, and the bottles were sealed with serum caps and shaken for 24 hr. Aliquots then were transferred to propylene centrifuge tubes by means of plastic syringes and centrifuged. Aliquots (1 ml) were withdrawn with polypropylene pipets and evaporated on planchets under an infrared lamp. A Duco cement-ethyl acetate mixture (1 ml) was then added to each planchet and also evaporated, after which the samples were counted. Aliquots (1 ml) of  $5.00 \times 10^{-5}$  M labeled TlClO<sub>4</sub> (prepared by diluting the 0.500 M stock solution of TlClO<sub>4</sub>) served as standards. It was necessary to use plastic ware, because it was found that glass adsorbed appreciable amounts of thallium. Several measurements were made with each precipitate, with a reproducibility of ca.  $\pm 5\%$  in the number of counts.

## Results

The solubilities of a variety of thallium(I) salts and potassium picrate in acetonitrile and water are compared in Table I.<sup>8-12</sup> The values listed for the halides

- (9) "International Critical Tables," Vol. IV, McGraw-Hill Book Co., Inc., New York, N. Y., 1928, p 220.
- (10) A. Seidell, "Solubilities of Inorganic and Metal Organic Com-

thiocyanate in acetonitrile were obtained by tracer measurements and were checked potentiometrically as described in the Experimental Section. The potentiometric data gave the following  $pK_{SP}$  values:  $TlCl$ , 12.4;  $TlBr$ , 12.4;  $TlI$ , 11.8; and  $TlSCN$ , 8.0. We used the tracer data, because of the uncertainty involved in estimating the activity coefficients required for the results of the potentiometric experiments, which were primarily designed to detect possible formation of anion complexes. The Stokes radii of  $I^-$  and  $Br^-$  are 2.33 and 2.37 Å, respectively,<sup>13</sup> and that for  $SCN^-$  is near 2.5 Å, as computed from the approximate values of Walden and Birr.<sup>14</sup> Hence, as before,<sup>7</sup> we use that  $a = 5$  Å in the Debye-Hückel equation. In a typical experiment with a mixture of  $5.0 \times 10^{-2}$  M triethylammonium halide and  $5.0 \times 10^{-3}$  M  $Tl(I)$  perchlorate,  $S \sim 4.5 \times 10^{-2}$ , assuming complete dissociation of the quaternary ammonium salt and no significant complexation beyond the first stage. (Actually, no complexation whatever was detected.) We obtain  $f_{\pm}^{\pm} = 0.35$ , a value which is enough to introduce considerable uncertainty. For further details, see ref 2.

### Discussion

**Medium Activity Coefficients.** It will be convenient here to refer to the activity coefficient of an ion in acetonitrile to its activity coefficient in water as standard state. The conversion factor required for this purpose is the medium activity coefficient,<sup>15</sup>  $\gamma_{i,AN}$ .

$$\gamma_{i,AN} = (\gamma_{i,AN})_0 (\gamma_{i,AN})_M \quad (1)$$

$(\gamma_{i,AN})_0$  is the conventional Debye-Hückel activity coefficient of the ion in acetonitrile relative to acetonitrile as standard state,<sup>7</sup> and  $\gamma_{i,AN}$  is the desired over-all activity coefficient. It is clear that the medium activity coefficient simply represents the free energy of transfer of the ion from acetonitrile to water.

$$\Delta G_i^\circ = G_i^\circ(AN) - G_i^\circ(W) = RT \ln \gamma_{i,AN} \quad (2)$$

For further information, refer to the discussions by Robinson and Popovych.<sup>16</sup>

Medium activity coefficients are tabulated in the last column of Table I for several anions. The numbers are on  $\log \gamma_{i,AN}$  values for  $Tl^+$  and  $K^+$  ions of 3.23 and 3.86, respectively, and a correction term of 0.36 for interconversion with the "aquamolality scale."<sup>17</sup> The immediate significance of medium activity coefficients can be illustrated as follows. Compare the activity of chloride ion in  $10^{-2}$  M solutions of lithium chloride in water and acetonitrile, referred in both cases to an infinitely dilute solution in water as standard state. In water,  $\gamma_{Cl^-,W} \sim 0.9$ ; hence,  $\gamma_{Cl^-,W} \sim 9 \times 10^{-2}$ . In acetonitrile,  $\gamma_{Cl^-,AN} \sim 0.8$  (calculated from the Debye-Hückel equation) and  $\gamma_{Cl^-} = 4 \times 10^{-2}$ ; hence,  $\gamma_{Cl^-,AN} \sim 3 \times 10^{-2}$ .

All anions tested, except perchlorate and picrate ions, favor water over acetonitrile as solvent. In water, anions are stabilized mainly by strong hydrogen bonding as a result of the localized positive charges of the water dipoles. Although the dipole moment of acetonitrile is high (3.37 D.), and in a nitrile the positive pole apparently is localized mainly on the cyanide carbon atom,<sup>17,18</sup> the charge density there is likely to be less than on the small water protons; in addition, a certain degree of charge delocalization nevertheless is likely to occur. Steric factors probably also impede solvation of anions by acetonitrile. Thus, because of the vicinity of the electron cloud of the  $C \equiv N$  bond, an anion probably will be forced to take up the specific position indicated in structure I, resulting in loss of freedom of rotation. Furthermore, solvation of a (small) anion by more than one acetonitrile molecule then becomes improbable. The same is not true for the cylindrically symmetrical solvate of a cation, indicated in structure II.

Direct measurement of the medium activity coefficient of fluoride ion is likely to be prone to large errors. Fluoride ion should be a very strong base in acetonitrile, and traces of acidic impurities (such as water) should cause a large increase in the solubility of sparingly soluble fluorides. However, it may be possible to estimate an approximate value for its medium activity coefficient from those of the other halide ions. A plot of  $\log \gamma_{X^-}$  vs. the reciprocal of the crystallographic radius is linear (Figure 1), which on extrapolation to  $r = 1.36$  Å gives  $\log \gamma_{F^-} \sim 14$ . The corresponding value for potassium ion, which has virtually the same radius (1.33 Å), is only 2.86, or 11 units smaller. On the other hand, iodide ion and a hypothetical alkali metal ion of the same radius should have approximately the same medium activity coefficient. These estimates illustrate one aspect of the strong differentiation in the properties of electrolytic solutes occurring in acetonitrile.

The two intercepts in Figure 1 predict that a hypothetical alkali metal ion with a radius near 13 Å (the exact value is uncertain) should have equal solvation energies in acetonitrile and water, and that for a halide ion the analogous radius is only 2.3 Å. We attribute the fact that neither value is infinity (which may have implications for Izmailov's splits; see below) to the influence of other factors, in addition to that which may be termed a first-order (Born) electrostatic effect. The polarizabilities of the ions, which increase rapidly with increasing radius, may be such an additional effect. The polarizability of a halide ion is greater than that of an alkali metal ion of equal radius, and the difference increases with increasing radius.<sup>19</sup> Hence, it is to be expected that this additional effect will cause equal solvation of a halide ion in the two solvents to occur

Figure 1. Dependence of medium activity coefficients of halide and alkali metal ions on radii.

at a smaller radius than would be the case for an alkali metal ion, as observed. Another factor which must be involved is the structure-making and structure-breaking properties of the ions in water.<sup>7</sup>

The very polarizable picrate ion is more stable in acetonitrile than in methanol, which has approximately the same dielectric constant, and in which  $\log_M \gamma_i = -1.1$ .<sup>16</sup> This is yet another illustration of the fact that the bulk dielectric constant of the solvent is not a very useful parameter in predicting the properties of solutes. The affinity of perchlorate ion for acetonitrile (or, more likely, its phobia for water) is puzzling.

The well-known fact that the solubility of a salt in acetonitrile (and other aprotic solvents) is particularly sensitive to the nature of the anion is clearly illustrated by the data in Table I.

It is obvious that it now becomes possible to calculate the solubilities of numerous salts in acetonitrile from the known values in water, by using the  $\log_M \gamma_i$  values for anions reported in Table I and those calculated from the shifts in potential given in the previous paper.<sup>7</sup> This will be true whether or not our original split of solvation energies into the ionic components was accurate. The only requirement is that for a given salt the sum of the two  $\log_M \gamma_i$  values be accurate.

Our results can be compared to two other estimates based on data appearing in the literature. Izmailov<sup>20</sup> split solvation energies of electrolytes into the ionic components by extrapolating plots of the solvation energies of the hydrogen halides, and of the differences in solvation energy between the hydrogen halides and the corresponding alkali metal halides, *vs.* the reciprocal of the radius of the varying ion to infinite radius; or, of appropriate combinations of solvation energies *vs.* the quantity  $1/n^2$  to  $n = \infty$ , where  $n$  is the principal quantum number involved. The following  $\log_M \gamma_i$  values were obtained:  $\text{Rb}^+$ , 1.6 (our value is 2.52);  $\text{Cl}^-$ , 8.0;  $\text{Br}^-$ , 5.0;  $\text{I}^-$ , 2.3. This split obviously indicates a greater difference between cation and anion activities than ours does. Izmailov's extrapolation is long and uncertain, a fact which undoubtedly contributes to the discrepancy (also see above).

(20) N. A. Izmailov, *Dokl. Akad. Nauk SSSR*, **149**, 1364 (1963).

Another estimate can be obtained from the solubility data of Pavlopoulos and Strehlow<sup>21</sup> for the alkali metal halides in acetonitrile. The rubidium halides<sup>22</sup> have the following molal solubilities<sup>23</sup> and molal mean activity coefficients,<sup>11</sup> respectively, in water:  $\text{RbCl}$ , 7.77, 0.58;  $\text{RbBr}$ , 7.04, 0.52;  $\text{RbI}$ , 7.72, 0.52. For acetonitrile the corresponding solubilities<sup>21</sup> and activity coefficients (calculated from the Debye-Hückel equation with  $a = 5 \text{ \AA}$ ) are:  $\text{RbCl}$ ,  $2.6 \times 10^{-4}$ , 0.95;  $\text{RbBr}$ ,  $2.6 \times 10^{-3}$ , 0.86;  $\text{RbI}$ ,  $8.0 \times 10^{-3}$ , 0.56. Using our values of 2.52 for  $\log_M \gamma_{\text{Rb}^+}$  and 0.36 for conversion to the aquamolality scale, we calculate  $\log_M \gamma_{\text{X}^-}$  values of 5.6, 3.5, and 1.0 for the halides, in reasonable agreement with the numbers in Table I.

**Liquid Junction Potentials.** Many polarographic measurements in acetonitrile (and other nonaqueous solvents) have been carried out with an aqueous saturated calomel electrode (*sce*) as reference. Various estimates have been made of the magnitude of the liquid junction potential (see pertinent papers listed in ref 7). Provided the mobilities in both solvents and the medium activity coefficients of all ions involved are known, it should be possible, in principle, to calculate the junction potential *ab initio*. This required information is now available (for  $\text{Et}_4\text{N}^+$ , we estimate  $\log_M \gamma_i \sim -0.3$  from the relative solubilities of  $\text{Et}_4\text{NI}$  in water and acetonitrile), but various other factors introduce gross uncertainties into such calculations. Typically we are dealing with the following complex interface

where the water phase may or may not contain agar. Furthermore, the exact profile of the interface is unknown (acetonitrile and water are miscible in all proportions). However, a semiempirical value of the junction potential can be obtained from our derived value of +0.503 v for the potential of the Pleskov electrode referred to the normal hydrogen electrode in water,<sup>7</sup> *i.e.*, +0.257 v referred to *sce*, and Iwamoto's experimental value of +0.291 v for the Pleskov electrode *vs.* *sce* with 0.1 M  $\text{Et}_4\text{NClO}_4$  as salt bridge.<sup>24</sup> The junction potential then is  $0.291 - 0.257 = 0.034 \text{ v}$ , of such sign as to make all potentials measured directly *vs.* *sce* too positive by 0.034 v. One may speculate that this relatively small value does not appear unreasonable in view of the marked compensating activity effects occurring across the interface. Thus, the medium activity coefficients of the four ions involved show qualitatively that the net effect is that the water phase is favored by an anion ( $\text{Cl}^-$ ), and the acetonitrile phase also by an anion ( $\text{ClO}_4^-$ ). Finally, it should be noted that, since potentials measured in acetonitrile against the *sce* certainly are reproducible to within a few milli-

provision of his laboratory facilities for the tracer measurements described in this paper. Financial support by the National Science Foundation under Grant No. GP-1479 is also gratefully acknowledged.

## Hydration of Undissociated Salts in Acetonitrile<sup>1</sup>

I. M. Kolthoff and M. K. Chantooni, Jr.

*Contribution from the School of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455. Received January 6, 1967*

**Abstract:** An equation has been derived to calculate from the total and ionic solubilities of potassium picrate, salicylate, 3,5-dinitrobenzoate, and 3,5-dinitrophenolate in acetonitrile (AN) in the presence of known concentrations of water the individual formation constants  $K^i_{(\text{MA})_w}$  and  $K^i_{(\text{MA})_{zw}}$  of dissolved, undissociated mono- and dihydrated salts,  $(\text{MA})_w$  and  $(\text{MA})_{zw}$ . Using these values and the previously determined values of formation constants of hydrated ions in AN, it has been possible to calculate the concentration of all species present in saturated solutions of the above salts in the presence of water. This allowed the calculation of the ionic dissociation constant  $K^d_{(\text{MA})_w}$  which was found to be greater than  $K^d_{(\text{MA})_s}$  (anhydrous salt). Unexplained is the result that  $K^d_{(\text{MA})_{zw}}$  of potassium salicylate was found smaller than the corresponding constant of the anhydrous salt. In the presence of water the dissociation constant of the anhydrous salt was found to be virtually unaffected up to a water concentration of 0.6 *M*. The red solid salt, potassium 3,5-dinitrophenolate, changes into a yellow solid in the presence of small concentrations of water in AN. This solid was found to be a monohydrate. No hydrated solid was formed with the other salts used. The ionic dissociation constant of the monohydrate was found greater than that of the anhydrous salt, while the constant of the dihydrate was found considerably greater than that of the monohydrate.

In a previous paper<sup>2</sup> the equilibrium constant of the hydration of several monovalent ions  $I^\pm$  was determined. In that study it was not necessary to consider a reaction between the dissolved undissociated anhydrous salt,  $(\text{MA})_s$  ( $M^+$  and  $A^-$  both being monovalent ions), and water.

In the present investigation the formation constants of the hydrates of the potassium salts of picric, salicylic, and 3,5-dinitrobenzoic acids and 3,5-dinitrophenol were determined. The potassium ion forms only a monohydrate with a formation constant of 1, while the sodium ion is much more strongly hydrated and forms at least a mono- and a dihydrate. For this reason sodium salts have not been used in the present study as they are expected to form higher hydrates than those of potassium. On the basis of the uncertainty in the assumptions made and in the experimental results, the hydration and dissociation constants calculated for sodium salts would be considerably more uncertain than those of hydrated potassium salts.

Denoting  $(\text{MA})_s$  as the unhydrated potassium salt and  $(\text{MA})_{zw}$  as the hydrated salts, the following equilibria can be written

From the total molar solubility,  $s_t$ , and the total ionic solubility,  $i_t$ , in presence of known concentrations of water eq 3 results,  $[\text{MA}]_s$  being the solubility of undissociated

$$s_t = i_t + [\text{MA}]_s + [\text{MA}]_{zw} \quad (3)$$

anhydrous salt in absence of water and  $[\text{MA}]_{zw}$  the total concentration of hydrated undissociated salts in presence of water. From the experimentally determined values of  $s_t$ ,  $i_t$ , and  $[\text{MA}]_s$ ,  $[\text{MA}]_{zw}$  is readily obtained. Assuming that the ratio of the solubility product and dissociation constant of  $(\text{MA})_s$ ,  $K_{sp}/K^d_{(\text{MA})_s}$ , equal to  $[\text{MA}]_s$ , does not change with water content, the values of the individual formation constants  $K^i$  of the hydrates (eq 1 and 2) are found from the relation

$$\frac{s_t - i_t - [\text{MA}]_s}{[\text{MA}]_s [\text{H}_2\text{O}]} = \frac{[\text{MA}]_{zw}}{[\text{MA}]_s [\text{H}_2\text{O}]} = K^i_{(\text{MA})_w} + [\text{H}_2\text{O}] K^i_{(\text{MA})_{zw}} \quad (4)$$

which is derived by combining eq 1–3. A plot is made of  $s_t - i_t - [\text{MA}]_s / [\text{MA}]_s [\text{H}_2\text{O}]$  vs.  $[\text{H}_2\text{O}]$ . If the slope of the linear plot is zero or close to zero, it is safe to conclude that  $y = 1$  and only a monohydrate is formed. When the linear plot does not have a slope of 0,  $y = 2$ , the intercept being equal to  $K^i_{(\text{MA})_w}$  and the slope  $K^i_{(\text{MA})_{zw}}$ .

From the experimental data it was also possible to calculate the dissociation constant of the salt  $(\text{MA})_w$  and of  $(\text{MA})_{zw}$  (eq 5 and 6). The over-all dissociation constant  $K^d_{z(\text{MA})_{zw}}$  (eq 7) is calculated in the follow-

tion constant  $K^d_{z(\text{MA})_{zw}}$  (eq 7) is calculated in the follow-

$$K^d_{z(\text{MA})_{zw}} = i_t^2 / s_t =$$

$$\frac{([M^+] + [M^+]_{zw}][A^-] + [A^-] + [A^-]_{zw})f^2}{[\text{MA}]_s + [\text{MA}]_{zw}} \quad (7)$$

(1) This work was supported by the Directorate of Chemical Sciences, Air Force Office of Scientific Research, under Grant AF-AFOSR-28-65.  
(2) M. K. Chantooni, Jr., and I. M. Kolthoff, *J. Am. Chem. Soc.*, **89**, 1582 (1967).

ing way. First  $[M_s^+]$  is calculated from the ionic solubility,  $i_t$ , taking the value of  $K_{K^+}^f$  equal to 1.0<sup>3</sup>. Then  $[A_s^-]$  is found from the solubility product,  $K_{sp}$  ( $K_{sp} = [M_s^+][A_s^-]^2$ ). From the values of  $[A_s^-]$  and the individual formation constants<sup>2</sup>  $K_{A_w^-}^f$  and  $K_{A_{2w}^-}^f$

$$K_{A_w^-}^f = [A_w^-]/[A_s^-][H_2O]$$

$$K_{A_{2w}^-}^f = [A_{2w}^-]/[A_s^-][H_2O]^2$$

$[A_w^-]$  and  $[A_{2w}^-]$  become known, while  $[MA]_w$  and  $[MA]_{2w}$  are calculated from the values of  $K_{(MA)_w}^f$  and  $K_{(MA)_{2w}}^f$  (eq 1 and 2) and  $[MA]_s$ . Finally  $K_{(MA)_w}^d$  and  $K_{(MA)_{2w}}^d$  are evaluated from eq 5 and 6.

Experiments have been carried out to check the assumption that the ionic dissociation constant of the unhydrated salt  $(MA)_s$  does not change in the presence of relatively small concentrations of water. For this purpose, water in known concentrations was added to a saturated solution of potassium salicylate in AN and the conductance measured. Using previously determined constants,  $K_{(MA)_s}^d$ , could be calculated, writing in eq 3 the total concentration  $C_s$  of the salt instead of  $s_t$ . From the relations

$$[K_s^+] = \frac{i_t}{1 + K_{K^+}^f[H_2O]} \quad (8)$$

$$[A_s^-] = \frac{i_t}{1 + K_{A_w^-}^f[H_2O] + K_{A_{2w}^-}^f[H_2O]^2} \quad (9)$$

and

$$[MA]_s = \frac{C_s - i_t}{1 + K_{(MA)_w}^f[H_2O] + K_{(MA)_{2w}}^f[H_2O]^2} \quad (10)$$

we obtain  $K_{(MA)_s}^d$  in the presence of water

$$K_{(MA)_s}^d = \frac{i_t^2 f^2 (1 + K_{(MA)_w}^f[H_2O] + K_{(MA)_{2w}}^f[H_2O]^2)}{(C_s - i_t)(1 + K_{K^+}^f[H_2O])(1 + K_{A_w^-}^f[H_2O] + K_{A_{2w}^-}^f[H_2O]^2)} \quad (11)$$

## Experimental Section

**Chemicals.** Acetonitrile was purified and dispensed as described previously.<sup>8</sup> Potassium picrate,<sup>4</sup> 3,5-dinitrobenzoate,<sup>5</sup> and 3,5-dinitrophenolate<sup>3</sup> were used previously while potassium salicylate was prepared in a similar way as the sodium salt.<sup>6</sup>

The monohydrate of potassium 3,5-dinitrophenolate was prepared and analyzed in the following way. Approximately 0.5 g of the red anhydrous salt was introduced into 10 ml of AN, the solution made 1.6 M in water, and the mixture shaken until equilibrium was obtained. The orange-yellow solid was collected by filtering with suction on a sintered-glass filter crucible and left exposed to the air until constant weight was attained (2 hr). The water content of the salt was determined by heating 412.2 mg at 110° to constant weight. The loss in weight corresponded to  $KA \cdot 0.96H_2O$ . A blank experiment in the absence of water gave a loss in weight of 0.7 mg for 402.0 mg of air-dried salt. Under the same conditions as above, 947.2 mg of air-dried potassium salicylate lost 0.6 mg upon drying at 110°, while in the blank experiment 902 mg of air-dried salt lost 0.2 mg. Apparently undissociated potassium salicylate is not hydrated in acetonitrile containing 1.6 M water.

**Ionic and Total Molar Solubility.** Ionic solubilities were obtained from the conductance of the saturated solutions as described previously.<sup>2</sup>

The total molar solubility,  $s_t$ , was found by taking a 1-ml aliquot of the saturated solution containing water, after filtering, evaporating to dryness under an infrared lamp, dissolving the residue in

0.3 ml of anhydrous acetic acid, adding 3 ml of AN, and titrating with 0.450 M perchloric acid in acetic acid using dibromothymol benzein as indicator. A very sharp color change from yellow to red was obtained at the end point.<sup>7</sup>

## Results

**Ionic Mobilities and Dissociation Constants of Salts.** The mobilities of the following ions were previously reported in AN; potassium, 86;<sup>8</sup> 3,5-dinitrobenzoate, 100;<sup>5</sup> 3,5-dinitrophenolate, 96;<sup>9</sup> salicylate, 78;<sup>6</sup> and picrate, 78.<sup>8</sup> It was found that with the exception of the picrate ion, the mobilities of the above ions did not change with the addition of water up to a concentration of at least 1.5 M.<sup>2</sup> The following values of the mobility of the picrate ion in the presence of water have been reported:<sup>2</sup> 0.55 M  $H_2O$ , 80; 1.94 M  $H_2O$ , 84; 2.13 M  $H_2O$ , 84; and 3.14 M  $H_2O$ , 84.

The dissociation constants and solubility products in anhydrous AN of the salts in Table I are: potassium picrate,<sup>4,8</sup>  $6.7 \times 10^{-3}$ ,  $2.8 \times 10^{-5}$ ; 3,5-dinitrobenzoate,<sup>5</sup>  $2.6 \times 10^{-4}$ ,  $5.3 \times 10^{-8}$ ; 3,5-dinitrophenolate,<sup>3</sup>  $3.6 \times 10^{-3}$ ,  $6.7 \times 10^{-6}$ ; and salicylate,  $1.4 \times 10^{-3}$ ,  $9.6 \times 10^{-6}$ , respectively. The dissociation constants of the latter two salts were estimated from the Fuoss and Kraus plot of conductivity data in Table II.

**Viscosity of AN in the Presence of Water.** The viscosity of AN solutions containing water<sup>2</sup> is 0.352 cp in 0.46 M  $H_2O$ ; 0.356 in 0.91 M  $H_2O$ ; 0.366 in 1.88 M  $H_2O$ ; and 0.382 in 3.13 M  $H_2O$ . All reported conductivities in the presence of water were corrected for viscosity.

**Total and Ionic Solubility of Salts.** Table I lists the total molar solubility,  $s_t$ , and total ionic solubility,  $i_t$ , at various concentrations of water up to 2 M in

saturated solutions of the various salts. From the experimental data  $K_{(MA)_s}^f$ ,  $K_{(MA)_{2w}}^f$ ,  $K_{(MA)_w}^d$ ,  $K_{(MA)_{2w}}^d$  (the latter only for potassium salicylate), and  $K_{Z(MA)_{2w}}^d$  (eq 7) were calculated as described in the introductory section, and the results are given in Table I. Values of  $K_{A_w^-}^f$  and  $K_{A_{2w}^-}^f$  reported in Table I have been taken from a previous publication.<sup>2</sup>

Of the salts in Table I potassium 3,5-dinitrophenolate is the only one which becomes hydrated in the solid phase. This occurs when the water concentration is equal to or greater than about 0.2 M. The product  $[M_s^+][A_s^-]^2$  then becomes smaller than  $K_{sp}$ . With the monohydrate as the solid phase, values of  $[M_s^+]$ ,  $[M_w^+]$ ,  $[A_s^-]$ ,  $[A_w^-]$ , and  $[A_{2w}^-]$  were found from the total ionic solubility,  $i_t$ , and the reported hydration constants of the ions, using eq 8 and 9, while  $[MA]_s$  was calculated from the experimentally determined value of  $s_t - i_t$  and the known value of  $K_{(MA)_w}^f$  using eq 10. The molarity of water reported in Table I has been calculated in all instances from the amount of water added and that removed by the various hydrated species.

Table III presents the conductance of solutions obtained by adding water to a saturated solution of potassium salicylate in anhydrous AN. The last column

lists the calculated values of  $K^d_{(KA)_n}$  in the presence of water (cf eq 10).

## Discussion

From the data in Table I it appears that undissociated potassium picrate does not become hydrated, at least up to a water concentration of 1 *M*. The most extensive study has been carried out with potassium salicylate. The solubility of this salt is great enough to determine the formation constants  $K^f_{(KA)_n}$  and  $K^f_{(KA)_{2n}}$  with reasonably accuracy. In the presence of 0.5 *M* or higher concentrations of water, the values of  $[MA]_w$  and especially  $[MA]_{2w}$  become considerably greater than the concentration of the unhydrated salt  $[MA]_s$ . It was expected that the ionic dissociation constants of the hydrated salts would be greater than that of the anhydrous salt due to the separation of center of charge on the cation and anion resulting from interposing one or two water molecules between them. This was found to be true for the monohydrate of potassium salicylate, its constant being of the order of  $4.5 \times 10^{-3}$  as compared to  $1.4 \times 10^{-3}$  for that of the anhydrous salt. Unexpectedly, the constant for the dihydrate was found to be  $0.8 \times 10^{-3}$  and smaller than that of the anhydrous salt. All calculations of the activity coefficients had been made using the limiting Debye-Hückel expression, which should yield only approximate values at the relatively high ionic strength of the solutions. All calculations were repeated using the extended Debye-Hückel expression

$$-\log f = \frac{1.53\sqrt{\mu}}{1 + (4.7 \times 10^7)a\sqrt{\mu}}$$

Using Kielland's<sup>10</sup> values in water for the ionic size *a* of potassium,  $3 \times 10^{-8}$  cm, and of salicylate,  $6 \times 10^{-8}$  cm, we obtain  $-\log f_{K^+} = 1.53\sqrt{\mu}/(1 + 1.41\sqrt{\mu})$  and  $\log f_{Sal^-} = 1.53\sqrt{\mu}/(1 + 2.82\sqrt{\mu})$ .

The values in parentheses in Table I refer to those calculated with the aid of the extended Debye-Hückel expression. The values of  $K^d_{(MA)_n}$ ,  $K^d_{(MA)_w}$ , and  $K^d_{(MA)_{2w}}$  remained unchanged. The data in Table III indicate that  $K^d_{(MA)_s}$  remains practically unchanged up to a water concentration of 0.6 *M*. All calculations in Table I were repeated taking into account the small effect of water on  $K^d_{(MA)_s}$ . The values obtained were almost the same as those reported in Table I up to a water concentration of 0.8 *M*. Considering the experimental uncertainty in the values of the four constants needed for the calculation of the dissociation constants and also the uncertainty in the assumptions made (especially that  $[MA]_s$  remains unaffected by water), the values for the dissociation constants of the hydrated forms of potassium salicylate are no more reliable than to within 50%. However, it is fair to conclude that the ionic dissociation constant of the

dihydrate is relatively small since its formation constant is large and the value of the "over-all" dissociation constant of potassium salicylate, reported in the last column of Table I, increases only very slightly with increasing water content because of formation of relatively large concentrations of the dihydrate. In the presence of 1.3 *M* water, the "over-all" dissociation constant is only twice as large as that of the unhydrated salt, while a similar "constant" of potassium 3,5-dinitrobenzoate was found to increase 15 times when the water concentration was 1.3 *M*.

The solubility product and the ionic dissociation constant of potassium 3,5-dinitrobenzoate in anhydrous AN are much smaller than those of the salicylate. In order to obtain results from eq 4 which are reasonably accurate it is necessary that  $s_i - i_i - [MA]_s = [MA]_{2yw}$  be considerably greater than corresponds to the experimental error in the determination of  $s_i$ ,  $i_i$ , and  $[MA]_s$ . This is not found to be the case with potassium 3,5-dinitrobenzoate. The sum of the concentrations of the three un-ionized hydrated forms  $[MA]_{2yw}$  is so small that the formation constant of each hydrate cannot be calculated. Only the "over-all" dissociation constant is found with good accuracy; it is found to increase very much with increasing water concentration (last column, Table I). The solubility product and ionic dissociation constant of anhydrous potassium 3,5-dinitrophenolate are of the same order of magnitude as the corresponding constants of the salicylate. At the low water concentrations where the solid phase is anhydrous salt, formation of undissociated dihydrated salt can be neglected, as its concentration is proportional to  $[H_2O]^2$ . At the three lowest water concentrations used a constant value of  $K^d_{(MA)_w}$  of  $6 \times 10^{-3}$  is found as compared to  $3.6 \times 10^{-3}$  for the anhydrous salt.

In saturated solutions, the monohydrate being the solid phase,  $[MA]_s$  is no longer constant, but it decreases with increasing concentration of water. On the other hand,  $[MA]_w$  is now a constant and equal to  $1.14 \times 10^{-3}$  *M* (Table I). Knowing  $K^d_{(MA)_w}$  and  $[K^+]$ , the value of  $[A_w^-]$  is readily obtained and found equal to  $2.8 \times 10^{-3}$  *M* at a water concentration of 0.55 *M*. From  $K^f_{(MA)_w}$  we obtain  $[MA]_s = 5 \times 10^{-4}$  and from  $K^d_{(MA)_w}$ ,  $[A_s^-] = 0.9 \times 10^{-3}$ . From eq 3 we get that  $[MA]_{2w}$  is  $2 \times 10^{-4}$  *M*. This small value is highly uncertain, but its order of magnitude should be correct. Using this value of  $[MA]_{2w}$  we obtain for  $K^d_{(MA)_{2w}}$  a value of the order of  $3 \times 10^{-3}$ , which is considerably greater than  $K^d_{(MA)_s} = 3.6 \times 10^{-3}$ . The formation constant of the dihydrate is of the order of 1.

The large increase of the "over-all" dissociation constant (last column, Table I) with increasing water concentration substantiates the conclusion that the dissociation constant of the dihydrate must be considerably greater than that of the anhydrous salt and greater than that of the monohydrate.

# Very Low-Pressure Pyrolysis. I. Kinetic Studies of Homogeneous Reactions at the Molecular Level

Sidney W. Benson and G. Neil Spokes

*Contribution from the Department of Thermochemistry and Chemical Kinetics, Stanford Research Institute, Menlo Park, California. Received September 19, 1966*

**Abstract:** Gases have been pyrolyzed in a very low-pressure environment in which attention has been given to the establishment of uniform temperature conditions, and energy transfer is predominantly *via* gas-wall collisions. We have compared the observed low-pressure and theoretical high-pressure decomposition rates of molecules of widely different chemical and structural character. Complicated molecules with small activation energies are pyrolyzed into simpler products at a rate which is close to the high-pressure rate. Simpler molecules decompose more slowly at rates which become controlled by energy transfer. Wall catalysis is relatively unimportant in the process. Studies of the unimolecular decomposition of isopropyl iodide have given information on: (1) the energy accommodation between wall and molecule, (2) the effective number of Kassel oscillators deduced from a simple theoretical treatment of the data, and (3) the effects of wall conditioning on the decomposition rate. The kinetic equations for the steady-state condition in a stirred flow reactor at very low pressures are evaluated explicitly. These include the effects of induction periods due to "mixing" and to lack of attainment of a steady-state internal energy distribution. Preliminary results on isopropyl iodide indicate that about 80 wall collisions are needed to attain steady state at 900°K.

A number of authors<sup>1-6</sup> have pyrolyzed complex molecules at sufficiently low pressures that there are very few gas-phase collisions, and most collisions take place with the walls of the vessels. The results of these studies have been useful as a means of producing radicals and, in one or two isolated instances, have given information about the initial molecular structure or isomerization. However, quantitative interpretation of the kinetics has proven difficult. Numerous reasons can be cited for this difficulty, but the principal reasons have been that the Boltzmann equilibrium has not been achieved in the reacting gas and the wrong equations have been applied to the data and have resulted in incorrect interpretation of the data. It is the purpose of the present and succeeding papers to describe a variant of these experimental techniques which lends itself to quantitative interpretation and thus provides a new kinetic tool for quantitative study of the details of unimolecular reactions, energy transfer, and bimolecular reactions in the gas phase. It can also be used to study heterogeneous reactions.<sup>7</sup> It is useful to refer to the technique as "very low-pressure pyrolysis" or "VLPP."

## Experimental Section

**Materials and Procedure.** The gas to be studied is stored in a reservoir at a few torr pressure. The gas passes through an

adjustable leak valve at a rate of from  $10^{15}$  to  $10^{16}$  molecules/sec and into the reactor through a short length of small bore capillary tube which prevents back diffusion from the reactor. Pyrolysis occurs in a cylindrical fused silica reactor approximately 9 cm long and 2.2 cm i.d. The ratio of internal surface area to exit-aperture area gives the average number of gas-wall collisions  $Z$ , made by a molecule while in the reactor. We have a number of reactors whose exit apertures are in the range of 0.8 to 0.008 cm<sup>2</sup>. A typical vessel is shown in Figure 1. A pair of 1-cm<sup>3</sup> fused silica baffles interrupt the direct path between the gas injection capillaries and the exit aperture. The pyrolysis vessel temperature is maintained to better than  $\pm 10^\circ$  up to 1000°. Heating is by means of a pair of 4-in. long clam shell heaters<sup>8</sup> with temperature "trimming" elements (each consisting of a coil of nichrome heating element) placed at the upper and lower parts of the furnace. Six chromel-alumel thermocouples monitor temperature at various parts of the vessel. The low thermal inertia system is lagged with Microquartz fiber to exclude drafts. (Microquartz<sup>9</sup> is a fabric composed of short, fine, quartz fibers; its properties are essentially unaffected by a Bunsen flame.) We have arranged for a sharp temperature gradient at the point of gas injection in order to heat the injected molecules as fast as possible. It is very important to avoid pyrolysis of the gas in the higher pressure region above this injection capillary. Gas density in the reactor depends on the area of the pyrolysis chamber exit aperture, on the degree of molecular decomposition achieved, and on factors such as molecular throughput, temperature, and molecular weight.

Gases which effuse from the reactor pass to the ionization chamber of a quadrupole mass spectrometer.<sup>10</sup> A schematic drawing of the apparatus is given in Figure 2. The spectrometer is located in a large (10-in. i.d. by 18-in. long) cylindrical aluminum chamber. Electrical connections are made by means of Kovar glass seals which are epoxied (using Epon 828 vacuum epoxy) to the aluminum support plate. An NRC HS4-750 pump (5-in. diffusion pump), using DC704 pump oil, evacuates the chamber through an ambient-cooled baffle and a 4-in. Temescal manifold gate valve. The base pressure of the system is about  $10^{-6}$  torr; a slight air leak gives peaks at 28 and 32 amu, and other residual gases give interference at 17, 18, 73, 77, 78, 91, and 135 amu and, less importantly, at numerous other places in the mass spectrum. A correction is applied when interference occurs. Ordinarily such interference is serious only when H<sub>2</sub>O, O<sub>2</sub>, or N<sub>2</sub> are produced and have to be measured explicitly. The effective pumping speed is about 60–80 l./sec in the

(10) Further details regarding the operating characteristics of the mass spectrometer will be supplied by the authors on request.

mass spectrometer chamber. The mass spectrometer consists of an ionizer, rod system, and particle multiplier tube fed by appropriate power supplies. Data are recorded by an oscilloscope-Polaroid camera combination.

The electronics which supply the quadrupole analyzer rods were designed by members of the Engineering Department of Stanford Research Institute.<sup>11</sup> The radiofrequency generator operates at a fixed frequency, and the mass spectrum is scanned by variation of applied voltage. A sawtooth signal from a waveform generator (Tektronix, Type 162) drives a dc amplifier and a coupled radio-frequency generator and, in addition, the signal drives or triggers

Figure 1. Very low-pressure pyrolysis fused silica reactor. Thermocouple locations are indicated by the numbers 1-6.

the horizontal sweep of the recording oscilloscope (Tektronix 535A). Linearity of mass-filtered *vs.* instantaneous voltage of the sawtooth gives a linear mass spectrum on the oscilloscope screen. The radiofrequency/dc ratio has to be maintained accurately in order to obtain a stable mass spectrum. Under normal operating conditions the electrical inputs to the analyzer rod system are adjusted until we get a mass spectrum whose relative peak heights are almost unchanged as the radiofrequency/dc ratio control (or resolution) is changed.

We have found it necessary to keep the electronics running at constant sweep rate in order to avoid drift effects<sup>12</sup> which appear when the quadrupole electronics are operated at fixed output (*i.e.*, when attempting to measure the intensity of a single peak). This has so far limited our precision to about  $\pm 5\%$ . We have found that best accuracy can be achieved by measuring adjacent or close-spaced mass peaks. For this reason, for example, work on *i*-PrI decomposition to  $C_3H_6$  and HI has been followed most easily by monitoring the peaks 39, 40, 41, 42, and 43. We think that our analytical methods cause errors of less than about 5% (in midrange) in the rate constants.<sup>13</sup>

(11) We are grateful to members of the Applied Physics group of Stanford Research Institute for the use of their designs of various parts of the quadrupole spectrometer and electronics.

(12) These drift effects seem to have been eliminated in a new set of electronics recently acquired from Electronic Associates Inc., Palo Alto, Calif.

(13) Other errors such as the determination of the escape rate constant of the reactor are comparable with this. A referee has pointed out that perhaps 10% of the material emerging from a 100-collision reactor will reenter the vessel and be subjected to further pyrolysis. All quoted rates for reactors of 93, 110, and 120 collisions should be reduced by about 10%.

For the work reported in this paper, no effective trapping had been provided between the diffusion pump and the mass spectrometer. It was thus necessary to heat the ionizer to a temperature of about 200° in order to maintain ionizer operation for as long as several days.

The ionizer is mounted approximately 7 cm from the furnace exit aperture. We estimate that less than 1.6% of the gas concentration in the ionizer is due to species which have arrived there from the reactor without making any collisions. The electron beam is directed at right angles to the analyzer rod system axis. Typically, operating pressures in the spectrometer chamber are below  $10^{-4}$  torr, and satisfactory signals are obtained with an electron beam current of about 2 ma at 70 ev. Interruption of the path between

Figure 2. Schematic of low-pressure pyrolysis apparatus.

furnace and ionizer by means of a beam flag has shown that only about 15-30% of the signal of the detector is due to gases which have just emerged from the reactor into the volume between the reactor exit aperture and the ionizer. These gas molecules will have already made a number of collisions with walls in the neighborhood of this volume. The bulk of the signal is given by gases which have made many collisions with the walls of the spectrometer chamber and have thus cooled to a low temperature. We do not, therefore, make any  $(T/M)^{1/2}$  correction to adjust for changing sensitivities for substances of different mass.

We have also noted that after a rapid change is made in the nature of the gases injected into the mass spectrometer, the spectrum may take some minutes to readjust to its new values. For example, when equimolar amounts of  $i$ - $C_3H_7I$  and  $C_3H_8$  are injected, several minutes must elapse after their introduction before reproducible runs are obtained. Similarly, when furnace temperature is raised so that the amount of decomposition is changed appreciably, a waiting time must be allowed for equilibration.

Some free-radical products such as  $CH_3$  cannot be detected directly with the present instrument, although their presence has been established by titration with  $NO_2$ . We are well aware of the problems attaching to direct detection of free radicals with mass spectrometers<sup>14</sup> and have not attempted to surmount them in this work.

## Results

**A. Pyrolysis of Selected Compounds.** The extent of decomposition of the reactant listed in Table I was followed by measuring the ratio of reactant peaks to product peaks. Where available, API<sup>15</sup> sensitivity data were used to estimate decomposition. When they were not available, estimates were made from the re-

\* Literature values of Arrhenius parameters are given in the second column. The temperatures (or their limits) at which 20 and 60% decomposition was observed are listed in the columns headed  $T_{20}$  and  $T_{60}$ . The terms  $k_u^{20}$  and  $k_u^{60}$  are the apparent first-order rate constants at  $T_{20}$  and  $T_{60}$ . (From the stirred flow reactor equations we have  $k_u^{20} = 0.2(1 - 0.2)^{-1}k_{\infty}$ , where  $k_{\infty}$  is the escape rate constant for the reactor.) The terms  $k_{\infty}^{20}$  and  $k_{\infty}^{60}$  are high-pressure rate constants at  $T_{20}$  and  $T_{60}$ , respectively. The ratio of  $k_u$  to  $k_{\infty}$  gives a measure of the fall-off. <sup>b</sup> Arrhenius parameters taken from compilation by S. W. Benson, "Foundations of Chemical Kinetics," McGraw-Hill Book Co., Inc., New York, N. Y., 1960. duction in parent peak intensity, using eq 17 of the Appendix. Species like di-*t*-butyl peroxide give unstable *t*-BuO radicals, which decompose completely in our system to acetone +  $\text{CH}_3$ . This makes them useful as sources of  $\text{CH}_3$  radicals. Extent of decomposition was determined from measurement of the ratio of mass peaks at 146 and 73 amu (parent compound) to that at 58 amu (acetone). Preliminary data on some of the reactions we have studied in a nominal 110-collision vessel are shown in Table I. Rather than give the entire decomposition curves, we have listed the temperatures at which we have observed 20 and 60% decomposition. For comparison we have given the high-pressure rate constants, using literature values for the Arrhenius parameters. We have used the equations for a stirred flow reactor to derive the apparent first-order rate constants from the per cent reaction. Details of the application of these equations to our system are developed in the Appendix.

In the cases of  $\text{CH}_3\text{I}$ ,  $\text{CHCl}_3$ , and toluene, we observed no measurable decomposition in this vessel up to the highest temperatures listed.

The mean molecular residence time in the vessel was about  $16(M/T)^{1/2}$  msec, where  $M$  is the mass in amu. For *i*-PrI, for example, this was about 6.5 msec at 1000°K.

**B. Isopropyl Iodide.** In order to check the validity of the results of VLPP for measurements of kinetics and energy exchange, we have studied the unimolecular decomposition of *i*-PrI in a number of vessels of different nominal collision numbers.

The unimolecular decomposition of isopropyl iodide and the inverse reaction (addition of HI to propene) have been thoroughly investigated by several groups of workers, and there is satisfactory agreement on the rate constants of the reactions.<sup>16,17</sup> For reaction i,  $k_{\infty} = 10^{12.30-42.5/\theta} \text{ sec}^{-1}$ , where  $\theta = 2.303RT$  (kcal/mole).

The error limits on log  $A_1$  are  $\pm 0.5$  and on  $E$  are

$\pm 1.0$  kcal/mole;  $k_{\infty}$  refers to the high-pressure rate constant.

Isopropyl iodide was pyrolyzed in our fused silica vessels at very low pressures. Gas flows were typically  $3 \times 10^{15}$  to  $5 \times 10^{15}$  molecules  $\text{sec}^{-1}$ ; except for the 9000-collision vessel, molecules made very many more collisions with the wall than with other molecules. For the 9000-collision reactor the mean free path for gas-gas collision was 4 cm compared with about 2 cm for gas-wall collisions. The decomposition rate was measured as a function of temperature for several vessels whose collision numbers  $Z_r$  were 93, 110, 630, 1100, and 9000.<sup>18</sup> The relative heights of the fragment peaks at 43 and 41 amu give an accurate measure of the amount of decomposition. These mass peak heights were measured after steady state had been reached at each temperature. The fraction of undecomposed material was calculated from our measurements of the relative sensitivities of these peaks, the parent compound, and propylene. (There is a small but important contribution to the 43 peak from  $\text{C}^{12}\text{-C}^{13}\text{H}_7^+$ .) A slight error is introduced into our results, since we cannot be sure that parent molecules will contribute to peaks 43 and 41 in the same way when the furnace is at a high temperature as they do when it is cold. This error could be significant when decomposition is less than 5%, but the approximation which ignores this correction should be satisfactory when decomposition is in excess of this amount.

From the kinetic equations which have been derived for the VLPP conditions, we compute apparent first-order rate constants  $k = k_e\delta$ , where  $\delta$  is the ratio of product to reactant fluxes and  $k_e$  is the known first-order rate constant for escape from our reactor.<sup>19</sup> Figure 3 shows log  $k$  as a function of temperature for the different reactors ( $k$  is in  $\text{sec}^{-1}$ ). Included for comparison is  $k_{\infty}$  calculated from the Arrhenius parameters.

Individual points in Figure 3 are averages of three or more observations. Each observation was made

(18) Collision number is given by the ratio of internal surface area to exit aperture area. All vessels were cylinders of 2.2 cm internal diameter and length about 9 cm.

(19) We estimate that for *i*-PrI in our vessels,  $k_e = 8.5A_h\sqrt{T} \text{ sec}^{-1}$ , where  $A_h \text{ cm}^2$  is the exit aperture area.

Figure 3. Apparent first-order rate constant for isopropyl iodide decomposition. The dimensions of  $k$  are  $\text{sec}^{-1}$ .

after short-term (*i.e.*,  $\sim 15$  min) reproducibility was obtained. Long-term (*i.e.*, on a day-to-day basis) reproducibility was generally fairly good on well-conditioned vessels. These included the 110-, 1100-, and 9000-collision reactors. The effect of history is illustrated for the less well-conditioned 630-collision reactor. Reactor temperature ( $^{\circ}\text{K}$ ) was increased in steps as follows: 300, 700, 800, 830, 898, 958, 1000, 1050, again 1050 after 90 min at temperature, 1148, and 1203. The temperature was then reduced to 1000 and then to 848 $^{\circ}\text{K}$ . (Except for the second run at 1050 $^{\circ}\text{K}$ , readings were ordinarily taken after 15 min at temperature.) Results for the 93-collision vessel are included for interest, although this reactor was previously unused. No conditioning studies were possible with this reactor, since it broke during a run at 1300 $^{\circ}\text{K}$ . Its "freshness" could account for the apparently fast rates compared with the 110-collision reactor.

A well-conditioned vessel differs visually from a fresh one; it is slightly darker in color. HF solution acts on the walls, causing a thin, dark (presumably carbonaceous) film to peel off. We have estimated that the percentage of material decomposing *via* carbon and other products is less than 10%.

## Discussion

The high-pressure rate constants approximately describe the observed results for the more complex molecules but are inadequate for the simpler ones in the 110-collision vessel. Further confirmatory work is required to clarify some of the data, particularly the fate of the radical species in the case of di-*t*-butyl peroxide decomposition. It is clear from the slowness of the rates found from the experimental data that

the walls are not "catalyzing" the reactions of the reactant molecules listed in Table I. The principal value of the work on the pyrolysis of this wide range of compounds was to eliminate our fear that wall reactions would seriously interfere with the pyrolysis. However, we would like to know the magnitudes of the relative roles of low-pressure falloff effects and of slowness of energy equilibration, for example. We have some indication of the importance of the latter process for *i*-PrI, but a comprehensive survey of all of these molecules would be of considerable general interest.

In order to unravel the various kinetic features from one another, we have developed, in the Appendix, a treatment of the theory of the method which we think is able to explain the data quantitatively.

Comparison of  $k_{\infty}$  for *i*-PrI with the observed rates confirms that energy transfer to the molecules limits the rate of decomposition.

Equations derived from the theory in the Appendix permit us to evaluate  $k$  from the classical Arrhenius parameters and from  $n$ , the effective number of internal oscillators in *i*-PrI. These theoretical values are shown in Figure 3 for  $n = 15$  and 18 and appear to bracket the experimental data very well except at the highest temperatures. It may be that the precision of our data warrants the more accurate RRKM<sup>20</sup> quantum theory, and we are exploring this possibility.

The difference in the rate constants for the 110- and for the 630- and 1100-collision vessels arises from the slowness of energy accommodation between wall and molecule which introduces an induction period, appreciable only for the smaller collision-number reactors. At 900 $^{\circ}\text{K}$  the energy required by an *i*-PrI molecule to undergo breakup in about  $10^{-4.3}$  sec is of the order of 60 kcal/mole or  $\sim 30RT$ . Accommodation to this energy seems to occur in  $80 \pm 30$  collisions.<sup>21</sup>

Wall-conditioning appears to be associated with the formation of a carbonaceous coating. The conditioning process could be associated with different energy-transfer processes between wall and reactant as the wall is progressively coated. The alternative view which cannot yet be ruled out is that the wall gives rise to catalytic decomposition of parent molecules. The occurrence of coating obviously implies that wall-promoted reactions can occur. Their rates are small, however, on our time scale, and it is more likely that these reactions are taking place with products than with reactants.

We are continuing our investigations of the nature of wall-conditioning effects and will report on these subsequently.

## Application of the Method

The possible applications of the low-pressure pyrolysis technique to chemical kinetics are manifold. By covering a large temperature range, we are able to measure apparent unimolecular rate constants  $k_d$  whose values range in each case over 4 to 6 decades (*e.g.*,  $10^{-2} < k_d < 10^{3.5} \text{ sec}^{-1}$ ). For most molecules studied, this carries  $k$  into the region well below the high-pressure limit rate constant  $k_{\infty}$ , and energy trans-

(20) D. W. Placzek, B. S. Rabinovitch, G. Z. Whitten, and E. Tschukow-Roux, *J. Chem. Phys.*, **43**, 4071 (1965).

(21) Calculated from theory presented in Appendix, eq 24.

s rate controlling. Using the theory with the experimental data, it is possible to obtain the Arrhenius parameters for  $k_{\infty}$  and the details of energy transfer, or with the walls or with added carrier gases. Studies of the induction times in low-collision-number systems yield values for the rates at which the upper additional levels of complex molecules relax in collisions. Such studies are now under way.

Perhaps the most important use for VLPP is in the study of the direct products of primary thermal reaction in unimolecular decomposition. Thus we have found that both 1- and 2-nitropropane decompose to give<sup>22</sup>  $C_3H_6 + HNO_2$ , rather than the much assumed  $n$ - or isopropyl radical +  $NO_2$ . We hope to distinguish the paths  $CHCl_3 \rightarrow CHCl_2 + Cl$  (or  $CH_2 + HCl$ ) in  $CHCl_3$  pyrolysis. Present data<sup>23</sup> indicate that carbene formation is important. We estimate that the activation energy exceeds 56 kcal.<sup>24</sup> Finally, the system lends itself extremely well to studies of the kinetics and stoichiometry of molecule-surface reactions, and we are now beginning studies of this type for suitable molecules with various catalytic and metal surfaces.

## Appendix. Treatment of Data

The experimental technique of very low-pressure pyrolysis (VLPP)<sup>25</sup> consists of permitting a steady-state flow of reactant molecules to pass into a thermodynamic reaction cell under conditions of such low pressure that most collisions of reactant (or product) molecules take place with the vessel walls and not in the gas phase. For our usual reactors this corresponds to pressures  $P \leq 10^{-2}$  torr. Once in the cell, reactant molecules may decompose, escape from the cell, or, in special cases, react chemically with added carrier gases or products. In conditioned quartz vessels, the rates of heterogeneous reactions have turned out to be small (less than 10% of the observed rates). This is not necessarily the case in metal vessels.

The apparent first-order rate constants measured in this system fall considerably below those obtained at higher pressures in static systems. In the following sections we shall develop the appropriate equations which permit us to interpret our data and explain qualitatively the falloff in rate constants in our system in similar ones.

**Flow Kinetics.** The conditions in VLPP correspond closely to those in a stirred flow reactor.<sup>26,27</sup> The important difference between the usual stirred flow reactor equation and those applicable here will emerge naturally. We can represent the mechanism by the following set of kinetic equations in which A represents reactant molecule and B represents an added carrier species (e.g.,  $NO_2$ ) or product molecule which can react with A (or the products of A).

where  $n_i$  is the stoichiometric number of moles of product formed per mole of A decomposing.

$(A)_{ss}$ , the steady-state concentration of A in the reactor, is determined by the rate of introduction  $N_A$  in moles/second (essentially the steady-state flow rate) and the various depletion processes. From the above we find

$$(A)_{ss} = \frac{N_A}{[k_{ea} + k + k_b(B)_{ss}]V} \quad (2)$$

where  $V$  is the reactor volume in liters and concentrations are in units of moles/liter. The steady-state concentration of species in the reactor thus depends on  $k_{ea}$  and  $k_b(B)_{ss}$ . These terms depend in turn on an average molecular speed, and there is thus this important difference between the stirred flow reactor equations for high and for very low pressures.

The flux of unreacted A in the exit stream is given by

$$Vk_{ea}(A)_{ss} = \frac{N_A k_{ea}}{[k_{ea} + k + k_b(B)_{ss}]} \quad (3)$$

The exit flux of product molecules P at steady state is

$$Vk_{ep}(P)_{ss} = k(A)_{ss}n_p V \quad (4)$$

where  $k_{ep}$  is the first-order escape rate constant for P.

The mass spectrometer is calibrated by passing known fluxes of products and reactants through the system. From the observed signals at two or more mass peaks, we can determine the relative fluxes of product and reactant. From eq 4, this relative flux  $\delta_p$  or  $\delta_q$  for product P or Q is given by

$$\delta_p = \frac{k_{ep}(P)_{ss}}{k_{ea}(A)_{ss}} = \frac{kn_p}{k_{ea}} \quad (5)$$

$$\delta_q = \frac{k_{eq}(Q)_{ss}}{k_{ea}(A)_{ss}} = \frac{kn_q}{k_{ea}} \quad (6)$$

where  $\delta_p$  and  $\delta_q$  are the ratios of the observed signals of P and Q, respectively, to A. We can write similar equations for  $\delta_r$  and  $\delta_s$ , the relative fluxes of R and S. From kinetic theory<sup>28</sup> the escape rate constant through a thin aperture is<sup>29</sup>

$$k_{ea} = \frac{1/4 \bar{c}_A A_h}{10^3 V} \text{ sec}^{-1} \quad (7)$$

where  $A_h$  is the hole area in  $\text{cm}^2$  and  $\bar{c}_A$  is the mean molecular speed of A. From kinetic theory  $\bar{c}_A = 1.46 \times 10^4 (T/M_A)^{1/2}$  cm/sec.  $M_A$  is the mass of A in amu. Hence, from eq 5 and 7

$$k = \frac{3.65 A_h \delta_p T^{1/2}}{V n_p M_A^{1/2}} \quad (8)$$

Using the relation  $Z_r = A_r/A_h$ , we can, if we wish,

(28) S. Dushman, "Vacuum Technique," 2nd ed, John Wiley and Sons, Inc., New York, N. Y., 1962, p 90. Equation 7 is derived from Dushman's eq 2.36 by dividing the pumping speed of the aperture by the vessel volume in liters.

(29) We may note that the escape rate constant is independent of gas pressure. This means that the volume effect treated by, for example, G. M. Harris (*J. Phys. Colloid Chem.*, 51, 505 (1947)) does not apply to VLPP conditions.

1 G. N. Spokes and S. W. Benson, manuscript in preparation.

2 S. W. Benson and G. N. Spokes, paper submitted to the 11th Symposium on Combustion, Berkeley, Calif., Aug 1966.

3 Assuming an  $A$  factor of  $10^{12.4} \text{ sec}^{-1}$  and a Kassel  $n$  of 7.5.

4 VLPP may be defined as "pyrolysis in a reactor at low pressure that energy transfer from an external heat source is primarily by way of gas-wall interactions. Gas flow is chiefly free molecular flow. Temperature history of average molecules is well characterized."

5 M. Bodenstein and K. Wolgast, *Z. Physik. Chem.*, 61, 422 (1908).

6 K. Denbigh, "Chemical Reactor Theory," Cambridge University Press, Cambridge, Mass., 1965.

rewrite  $k$  in terms of the vessel collision number  $Z_r$  and the internal surface area of the vessel  $A_v$  (cm<sup>2</sup>)

$$k = \frac{3.65\delta_p A_v T^{1/2}}{V n_p M_A^{1/2} Z_r} \quad (9)$$

Now

$$\frac{\delta_p}{n_p} = \frac{\delta_q}{n_q} = \frac{f}{(1-f)} \quad (10)$$

where  $f$  is the fraction of unimolecular decomposition of A in the reactor.

From eq 5 and 10

$$k = k_{ea} \frac{f}{(1-f)} \quad (11)$$

From eq 9 and 10

$$k = \frac{3.65 A_v T^{1/2}}{Z_r V M_A^{1/2}} \left[ \frac{f}{(1-f)} \right] \quad (12)$$

It will be noted that eq 11 and 12 bear a formal similarity to the equations for a stirred flow reactor.<sup>30</sup>

If  $f'$  represents the fraction of A disappearing by chemical reaction with B, we can show that

$$k_b(B)_{ss} = \frac{3.65 A_v T^{1/2} [f'/(1-f')]}{Z_r V M_A^{1/2}} \quad (13)$$

Here  $f'/(1-f')$  is a direct experimental observable and is equal to  $\delta_r/n_r$  or  $\delta_s/n_s$ .

Since our experimental data give  $f/(1-f)$  and  $f'/(1-f')$  directly, we can immediately use eq 12 and 13 to give first-order and second-order rate constants.

Some experiments are not directly amenable to the foregoing treatment. For example, we may sometimes not be able to measure the relative sensitivities of a parent molecule and its free-radical decomposition products. For such experiments we must measure the absolute flux of parent molecules under the various experimental conditions.

The mass spectrometer signal  $I_A$  is closely proportional to the flux of species A. If we denote the constant of proportionality (or sensitivity) by  $\alpha_A$ , then (with eq 2)

$$I_A = \alpha_A k_{ea}(A)_{ss} = \frac{N_A k_{ea} \alpha_A}{k + k_{ea} + k_b(B)_{ss}} \quad (14)$$

We can determine  $\alpha_A$  by calibration.<sup>32</sup>

In this type of measurement  $N_A$ , the mass flow rate, is kept constant and the temperature range is scanned. At low temperatures where no reaction takes place, we observe a signal  $I_A^0 = N_A \alpha_A$  (from eq 4) so that we can eliminate  $N_A$  and  $\alpha_A$  and write

$$\frac{I_A}{I_A^0} = \frac{k_{ea}}{[k + k_{ea} + k_b(B)_{ss}]} \quad (15)$$

(30) Equation 12 can be transformed to eq 10 of ref 31 by the substitutions  $k/k_w = b$ ,  $f = B$ , and  $Z_r = v_m$ .  $k_w$  is the wall-collision frequency where  $k_w = 3.65 A_v T^{1/2} / (V M_A^{1/2})$  sec<sup>-1</sup>.

(31) P. LeGoff, *J. Chim. Phys.*, 359 (1956).

(32) One must correct for the effect of oven temperature on  $\alpha_A$  when working with molecular beams. This problem has been studied by O. Osberghaus and R. Taubert, *Z. Physik. Chem. (Leipzig)*, B516, 264 (1955); H. Ehrhardt and O. Osberghaus, *Z. Naturforsch.*, 13a, 16 (1958); 15a, 575 (1960). The mass spectrometer experiments described earlier in this paper were not beam experiments and most of the molecules were cooled to close to ambient temperature prior to entering the ionizer.

Solving for  $k$ , the apparent first-order rate constant for decomposition of A, we find

$$k = k_{ea} \left[ \left( \frac{I_A^0}{I_A} \right) - 1 - \frac{k_b(B)_{ss}}{k_{ea}} \right] \quad (16)$$

In the absence of any secondary reactions by B, we have

$$k = k_{ea} \left[ \left( \frac{I_A^0}{I_A} \right) - 1 \right] = k_{ea} \left( \frac{I_A^0 - I_A}{I_A} \right)$$

or, alternatively

$$k = k_{ea} \frac{f}{(1-f)} \quad (17)$$

**2. Induction Periods.** Two types of induction times must be considered in our system. The first,  $\tau_m$ , corresponds to a "mixing" time and arises because reactant molecules are introduced at one end of a cylindrical vessel and escape from an orifice at the opposite end. The probability of escape is lower for these molecules than for the average molecule, and one can make a simple estimate that in time  $\tau_m$ ,  $Z_m$  collisions are required to bring these molecules to an "average" position in our cell. For a cylinder of length  $l$  cm and radius  $r$  cm,  $Z_m \sim (l/2r)^2$ .  $Z_m$  is estimated on the basis of a random walk of step size  $r$  cm. For our system  $Z_m$  is about 4 to 6 and generally negligible.

The second induction period is related to the time  $\tau_1$  necessary to reach the stationary population of the upper vibrational levels of the reactant molecules. Since internal energies of average reacting molecules are in the range of  $40RT$ , one would imagine that on the order of at least 40 and possibly  $(40)^2$  wall collisions would be required to establish such stationary states.

We can examine the effect of this internal energy relaxation by considering the fate of a number of molecules  $V(\Delta A)$  introduced into the reactor at time  $t = 0$  in a time interval  $\Delta\tau$  which is very short compared to the mean residence time  $\tau_r$  in the reactor. Note that  $\tau_r = 1/(k_{ea} + k)$ .

Ignoring the complications of secondary reactions with B, the rate of depletion of the group  $\Delta A$  in the reactor is given by

$$\frac{-d(\Delta A)}{dt} = (k + k_{ea})(\Delta A) \quad (18)$$

where  $k$  is now some monotonic function of time. If we wish to take account of the mixing time  $\tau_m$ , we can easily do so by saying that  $k_{ea}$  is a step function,  $k_{ea} = 0$  for  $0 \leq t \leq \tau_m$ , and  $k_{ea} = k_{ea}$  for  $t \geq \tau_m$ , with  $\tau_m = Z_m \tau_w$  where  $\tau_w$  is the mean time between wall collisions.

Integrating eq 18 between limits 0 and  $t$ , we find

$$-\ln \left[ \frac{(\Delta A)}{(\Delta A)_0} \right] = k_{ea}(t - \tau_m) + \int_0^t k dt \quad (19)$$

$$= k_{ea}(t - \tau_m) + \langle k \rangle t \quad (20)$$

where  $\langle k \rangle$  is the average of  $k$  over the time interval  $t$  and is a function of  $t$  as defined by eq 19 and 20.

Now the rate of unimolecular reaction is given by

$$-\left[ \frac{d(\Delta A)}{dt} \right]_{\text{chem}} = k(\Delta A) \quad (21)$$

and, on eliminating  $(\Delta A)$  with the aid of eq 20

$$\frac{-1}{(\Delta A)_0} \left[ \frac{d(\Delta A)}{dt} \right]_{\text{chem}} = k \exp\{-[k_{\text{ea}}(t - \tau_m) + \langle k \rangle]\} \quad (22)$$

The total fraction of chemical reaction  $f$  which occurs in the group  $\Delta A$  is obtained by integrating eq 22 between limits  $0 \leq t \leq \infty$ . We find

$$f = \exp(k_{\text{ea}}\tau_m) \int_0^\infty k \exp[-(k_{\text{ea}} + \langle k \rangle)t] dt \quad (23)$$

This can be integrated if we have an explicit form for  $k(t)$ . As a simple case which is probably not far from reality, we may assume that  $k$  is a step function such that  $k = 0$  for  $0 < t < \tau_i$  and  $k = k$  for  $t \geq \tau_i$ .  $\tau_i$  is then an induction time for energy relaxation. Under these conditions  $f$  becomes

$$f = \frac{k \exp\{-k_{\text{ea}}(\tau_i - \tau_m)\}}{(k_{\text{ea}} + k)} = \frac{k/\beta}{(k_{\text{ea}} + k)} \quad (24)$$

with  $\beta \equiv \exp\{k_{\text{ea}}(\tau_i - \tau_m)\}$  and generally  $\beta \geq 1$ .

Solving for  $k$  we find a result similar to eq 11

$$k = \frac{k_{\text{ea}}\beta}{(1 - f\beta)} \quad (25)$$

where  $f\beta$  can be interpreted as a corrected fraction of decomposition.

In vessels with very small apertures where  $k_{\text{ea}}(\tau_i - \tau_m) \ll 1$ , eq 11 and 25 are identical, and we can ignore the induction times. This permits us to solve for  $k$  from calculations of  $k_{\text{ea}}$  (eq 7) and measurement of  $f$ . We can then solve for the induction parameters (from eq 24) by measuring  $f$  at the same temperatures in a series of vessels of different  $k_e$  where  $k_e(\tau_i - \tau_m) \approx 1$ .

From preliminary results reported here, it appears as though for isopropyl iodide, at about 1000°K,  $(\tau_i - \tau_m) \sim 4$  msec in a conditioned quartz vessel. This would correspond to about 80 wall collisions for the average *i*-PrI molecule to pick up about  $40RT$  of internal energy. If we assume an oversimple Brownian process of energy exchange between the walls and *i*-PrI molecules, this corresponds to about  $4.5RT = 9$  kcal/mole transfer of energy per wall collision, essentially a "strong" collision mechanism.<sup>33</sup>

**3. RRK Theory of the Unimolecular Rate Constant  $k_u$ .** The Rice-Ramsperger-Kassel (RRK) theory of unimolecular reactions assumes that molecules are activated and deactivated by collisions and that a stationary population of vibrationally excited species is produced by these processes together with the process of spontaneous unimolecular decomposition. The rate constant falls off from its high-pressure limit when spontaneous decomposition depletes the upper energy states responsible for reaction faster than collisional deactivation does.

Normally, one studies such effects by measuring the apparent first-order rate constant at fixed temperature but successively lower pressures. In the VLPP technique, the frequency of wall collisions is essentially fixed by the dimensions of the vessel. As one goes to higher and higher temperatures, the rate of spontaneous decomposition increases, and at sufficiently high temperatures all unimolecular reactions will fall off from their high-pressure limits.

(33) G. H. Kohlmaier and B. S. Rabinovitch, *J. Chem. Phys.*, **38**, 1692 (1963).

For an arbitrary reactant molecule A, the RRK scheme is<sup>34</sup>

Here  $k_a$  and  $k_d$  are rate constants for vibrational energy exchange at the wall, and  $k_r$  is the specific decomposition rate of a critically energized molecule with internal energy  $E \geq E^*$ , the activation energy for reaction at 0°K. The observed apparent first-order rate constant  $k$  is then

$$k = \int_{E^*}^\infty \frac{k_a k_r}{k_d + k_r} dE \quad (27)$$

Using the classical RRK forms for  $k_r$  and  $k_a/k_d$ , it can be shown that the integrand in eq 27 has a simple sharp maximum at  $E = E_m$  where  $E^* \leq E_m \leq E^* + (n - 1)RT$ , and  $n$  is the effective number of classical oscillators in the molecule A. If the half-width of the integrand is  $\Delta E_m$  around the maximum, then we can write

$$k = \frac{k_a(E_m)k_r(E_m)(\Delta E_m)/RT}{[k_d(E_m) + k_r(E_m)]} \quad (28)$$

It can be further shown that this maximum occurs very close to the value of  $E_m$  that makes  $k_d(E_m) \sim k_r(E_m)$ , so that eq 28 becomes

$$k \approx \left(\frac{k_a}{2}\right) \frac{(\Delta E_m)}{RT} = \left(\frac{k_a}{k_d}\right) \left(\frac{k_d}{2}\right) \left(\frac{\Delta E_m}{RT}\right) = \frac{1}{2} P(E_m) k_d \frac{\Delta E_m}{RT} \quad (29)$$

where  $P(E_m) = k_a/k_d$  is the probability of finding a molecule of internal energy  $E_m$  in a system at equilibrium. It is given classically by

$$P(E_m) = \frac{1}{(n - 1)!} \left(\frac{E_m}{RT}\right)^{n-1} \exp\left(-\frac{E_m}{RT}\right) \quad (30)$$

Now  $k_d(E_m)$  can be written as  $\lambda_d k_w$ , where  $k_w$  is the frequency of wall collisions, typically  $\sim 10^{4.5} \text{ sec}^{-1}$  in our system, and  $\lambda_d$  is the probability that a molecule with internal energy  $E_m$  will, on a wall collision, lose enough of this energy that it is not capable of reacting in  $10^{-4.5} \text{ sec}$ . The amount of energy required is probably of the order of  $2RT$  and  $\lambda_d$  is probably of the order of 1. Thus we can set

$$k_r(E_m) = k_d(E_m) \cong k_w \quad (31)$$

while from the RRK theory

$$k_r(E_m) = A \left( \frac{E_m - E^*}{E_m} \right)^{n-1} \quad (32)$$

where  $A$  is the Arrhenius  $A$  factor in  $\text{sec}^{-1}$ . From eq 31 and 32

$$1 - \frac{E^*}{E_m} = \left( \frac{k_w}{A} \right)^{1/(n-1)} \quad (33)$$

or

$$\frac{E^*}{E_m} = 1 - \left( \frac{k_w}{A} \right)^{1/(n-1)} \quad (34)$$

(34) S. W. Benson, "Foundations of Chemical Kinetics," McGraw-Hill Book Co., Inc., New York, N. Y., 1960, Chapter XI.

Thus if we know or can choose a value of  $n$  and  $A$  we can calculate the ratio  $E^*/E_m$  for our system.

Having calculated the ratio  $(E^*/E_m)$ , one then uses eq 29 and 30 with  $\Delta E_m/RT \sim (n-1)^{1/2}$  to calculate  $E_m$  at any given temperature.<sup>35</sup> This is done numerically, explicit solutions not being possible.

With Stirling's approximation for  $(n-1)!$  we have from eq 29 and 30

(35) This approximation for  $\Delta E_m$  is obtained by use of the method of steepest descents for the integration of eq 29.

$$k = \frac{k_w}{2\sqrt{2\pi}} \left[ \frac{eE_m}{(n-1)RT} \right]^{n-1} \exp\left(-\frac{E_m}{RT}\right) \quad (35)$$

which permits us to solve for  $E_m$  from the observed value of  $k$  and the appropriate value of  $n$ .

When the high-pressure Arrhenius parameters  $A$  and  $E^*$  are known, as is often the case,  $n$  is the only unknown parameter and it can be determined accurately.

We have used eq 35 in our theoretical estimates for the rate of decomposition of *i*-PrI.

## A Nuclear Magnetic Resonance Study of Steric Effects in *cis*- and *trans*-1,4-Dichloro-2-butene<sup>1</sup>

Harry G. Hecht<sup>2</sup> and Bob L. Victor

Contribution from the University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico, and the Department of Chemistry, Texas Technological College, Lubbock, Texas. Received December 16, 1966

**Abstract:** The 60-Mc nmr spectra of *cis*- and *trans*-1,4-dichloro-2-butene are reported and analyzed. A population analysis based upon the observed vicinal couplings indicates that the steric interaction between  $-\text{CH}_2\text{Cl}$  groups in the *cis* isomer is at least 170 cal mole<sup>-1</sup> larger when the chlorine atom is oriented *trans* with respect to the adjacent vinyl proton.

The nuclear spin-spin coupling between vicinal protons in  $\text{HC}-\text{CH}$  groups of ethane and ethylene-type molecules has been found to be dependent upon the dihedral angle.<sup>3</sup> Since internal rotational energy barriers about carbon-carbon single bonds are low, only an average coupling is observed in many cases, but such an average can still be useful to determine which is the more stable rotamer.

The analysis of the complex nmr spectra of *cis*- and *trans*-1,4-dichloro-2-butene was undertaken since the coupling constants obtained from these spectra can be used to infer the conformation of the  $\text{CH}_2\text{Cl}$  groups about the carbon-carbon single bonds. Our primary objective was to see if we could determine the extent of the steric interaction of these groups in the *cis* compound.

The basis for our conformational study rests upon the following considerations. Figure 1 shows the anticipated stable conformation of *trans*-1,4-dichloro-2-butene.<sup>4-6</sup> It is assumed that in this case a certain average vicinal coupling between the methyl protons ( $\text{H}_a$ ) and the adjacent vinyl proton ( $\text{H}_b$ ) will be observed, the magnitude of which is determined by the energy difference between the conformation of Figure 1 and others obtained by rotations about the carbon-carbon single bonds. If the same *trans* orientation of an  $\text{H}_a$

proton with respect to the adjacent  $\text{H}_b$  proton persisted in the *cis* isomer, we would expect to observe a rather strong steric interaction between the  $\text{H}_a$  protons of the different  $-\text{CH}_2\text{Cl}$  groups. Of course with the chlorine atoms *trans* with respect to  $\text{H}_b$ , the steric effect would be even more pronounced. Because of these interactions, conformational stability requirements are altered, and these changes should be reflected in the average proton couplings observed.

This unsaturated system may be regarded as an allylic system, since there is spin-spin coupling between protons separated by one double bond and three single bonds, and also as a homoallylic system, where the coupling between protons is over five bonds with the protons symmetrically placed about the carbon-carbon double bond, *i.e.*,  $\text{H}-\text{C}-\text{C}=\text{C}-\text{C}-\text{H}$ .<sup>7</sup>

Karplus,<sup>8</sup> through a valence bond treatment, has had most success in correlating experimental results with theoretical calculations, with respect to both the sign and magnitude of couplings in allylic and homoallylic systems. The proposed mechanism involves hyperconjugation determined by  $\sigma-\pi$  configuration interaction.

From the theoretical point of view, the allylic coupling constants are negative in sign with the coupling being transmitted mainly through the  $\pi$ -electron system.<sup>8</sup> The magnitudes of the allylic coupling constants have been found to vary between 0 and 3 cps.<sup>9</sup> These coupling constants attain a maximum of approximately 3 cps when the azimuthal angle is 90°, and a minimum when the azimuthal angle is 0 or 180°.

In the homoallylic system the coupling also involves the  $\sigma$ - $\pi$  configuration interaction mechanism.<sup>8</sup> The theory predicts the sign to be reversed, but there should be no change in the magnitude of the coupling constants on replacing the fragment C=C by C=C-CH. The same stereochemical limitations should apply as for the allylic case.

### Experimental Section

**Preparation of Compounds.** *trans*-1,4-Dichloro-2-butene was obtained from K and K Laboratories Inc. as a 98% pure compound. *cis*-1,4-Dichloro-2-butene was synthesized following the procedure of Babbitt, Amundsen, and Steiner.<sup>10</sup> Attempts to purify these compounds by distillation and fractional crystallization were unsuccessful, but through the courtesy of Dr. G. Perkins, Jr., of Continental Oil Co., both compounds were finally purified using gas chromatography.<sup>11</sup> The chromatogram indicated that the *trans* compound was contaminated with about 18% of impurities before purification.

Before observing the nmr spectra of the liquid samples of *cis*- and *trans*-1,4-dichloro-2-butene, these samples were degassed by flushing with nitrogen gas in standard thin-walled cells. Sealed capillaries of benzene were inserted into the sample tubes for use as an external reference standard. There were no bulk susceptibility corrections made.

**Instrumentation.** The nmr spectra were recorded on a Varian A-60 spectrometer operating at room temperature. The line positions were measured at total peak height with a probable error of  $\pm 0.05$  cps.

The spectra were calculated using a computer program written for an IBM 1620 Model II computer having a disk pack. The computer program was written in FORTRAN II following the procedure given by Pople, Schneider, and Bernstein.<sup>12</sup> Values for the chemical shift for each proton plus the coupling constants between the various protons in the molecule are used as parameters to calculate the spectrum. By varying these parameters the experimental spectrum was fairly well reproduced. The probable error for the calculation of the frequencies and intensities is 0.05 to 0.1 cps. Thus we feel that the chemical shifts and coupling constants determined in this way are accurate to at least  $\pm 0.1$  cps.

### Results

The calculated chemical shifts and coupling constants for the *cis* and *trans* isomers as determined by the methods discussed above are found in Tables I and II, respectively. The results are illustrated in Figures 2 and 3. The field is calibrated in cycles per second from the benzene external standard.

The results obtained are in agreement with the theory as well as with the results obtained by other investigators.<sup>7</sup> The small but significant differences in the allylic, vicinal, and long-range coupling constants for the two isomers can be used to discuss conformational effects. Since the vicinal coupling is the more straightforward, we will limit our subsequent discussion to it.

A complete conformational analysis is complicated by the fact that much less experimental data are available in the case of orientations about a carbon-carbon single bond which involves  $sp^3$  hybridization on one end and  $sp^2$  hybridization on the other. However, both theoretical<sup>13</sup> and experimental<sup>14</sup> indications are that the angular dependence of the vicinal coupling constant closely parallels that found for  $sp^2$ - $sp^2$  hybridization.

III

Figure 1. Assumed conformation of *trans*-1,4-dichloro-2-butene.

Figure 2. The experimental and calculated 60-Mc nmr spectrum of *cis*-1,4-dichloro-2-butene.

A population analysis based upon the three conformations I–III leads to an average vicinal coupling constant

$$J = p_I J_t + (1 - p_I) J_g$$

where  $J_t$  and  $J_g$  are the *trans* and *gauche* couplings, and the fractional populations are  $p_I$ ,  $p_{II}$ , and  $p_{III}$  ( $p_I + p_{II} + p_{III} = 1$ ).

We assume the values of  $J_t = 13.4$  cps and  $J_g = 2.4$  cps reported by Bothner-By, *et al.*,<sup>15</sup> for the vicinal *trans* and *gauche* couplings in allyl chloride. Then we find for the *trans* configuration ( $J = 7.1$  cps)  $p_I = 0.427$ , and for the *cis* configuration ( $J = 7.9$  cps)  $p_I = 0.500$ . If we assume, as is usually done,<sup>15</sup> that  $\Delta S =$

(15) A. A. Bothner-By, S. Castellano, S. J. Ebersole, and H. Günther, *J. Am. Chem. Soc.*, **88**, 2466 (1966).

Figure 3. The experimental and calculated 60-Mc nmr spectrum of *trans*-1,4-dichloro-2-butene.

0, then the energy difference in the conformers I or II and III is

$$\Delta H = -RT \ln K_{eq} = -RT \ln \frac{2p_I}{1 - p_I}$$

We find in this way that  $\Delta H_{trans} = -237$  cal mole<sup>-1</sup> and  $\Delta H_{cis} = -411$  cal mole<sup>-1</sup>. The difference,  $\sim 170$  cal mole<sup>-1</sup>, represents a lower limit to the difference in energy of interaction of a proton and a chlorine atom in the *trans* orientation (with respect to the vinyl proton) with the average potential of a  $-\text{CH}_2\text{Cl}$  group oriented *cis* (with respect to the other  $-\text{CH}_2\text{Cl}$  group).

The fact that this figure is but a lower limit is shown by the value of  $p_I = 0.5$  for the *cis* compound, which means that  $p_{III} = 0$  and  $J = (J_t + J_g)/2$ . Obviously, all that we can determine is the least amount of interaction energy which is required to drive the system to this limit. It is also possible that there may be some skewing of the stable conformation due to the steric interaction, similar to that reported by Woolfenden and Grant<sup>16</sup> for *o*-methyl groups in aromatic systems. Whether or not this effect is significant should be revealed by a study of the parent compounds, *i.e.*, the *cis*- and *trans*-2-butenes, where no population effects are involved. Such a study is being pursued by us at the present time.

# Halogen Atom Complexes. Thermodynamic and Kinetic Properties of the Iodine Atom-*o*-Xylene Charge-Transfer Complex

Robert L. Strong and Jeanne Perano

Contribution from the Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181. Received December 30, 1966

**Abstract:** Thermodynamic and kinetic properties of the transient complex between iodine atoms and *o*-xylene in the liquid phase have been determined by flash spectrophotometry. The formation constant and enthalpy of formation at 25° are reasonably consistent with those inferred from kinetic recombination studies for the gas-phase complex when solvation effects are considered, and show that charge-transfer interactions can lead to both the specificities and observed negative temperature coefficients for relatively efficient third-body species.

The homogeneous gas-phase recombination of halogen atoms (X) in the presence of a third body (M) is now generally considered<sup>1</sup> to occur either by the energy-transfer mechanism

or the radical-molecule complex mechanism

In these mechanisms,  $XX^*$  represents a short-lived diatom with more than sufficient energy to dissociate, and  $XM$  is a complex of sufficiently long life to be collisionally deactivated and to participate in step 4, leading to recombination

the over-all rate of recombination in either case being

$$\frac{d[X_2]}{dt} = k_{app}[X]^2[M] \quad (5)$$

The first mechanism satisfactorily describes the recombination of iodine atoms in the presence of atomic or relatively simple molecular third bodies.<sup>2</sup> In more complex systems, however, the large rate constants cannot adequately be explained by energy transfer alone, and the second mechanism accounts for recombination where the binding energy of  $XM$  is greater than  $kT$ . Dispersion forces alone, although leading to reasonable binding energies,<sup>3,4</sup> do not result in the large variations actually observed in third-body efficiencies,<sup>4-6</sup> whereas charge-transfer interactions lead to quite large binding energies but reasonable specificities among the donor third bodies.

Following the flash photolysis of molecular iodine, a transient absorption attributed to a strong intermediate complex between a nitric oxide molecule and an iodine atom has been detected in the gas phase.<sup>7</sup> Similarly, charge-transfer complexes between iodine atoms and aromatic donors have been observed spectrophotometrically in the liquid phase;<sup>7-9</sup> the absorption spectra of these relatively weak complexes have not been observed in the gas phase, but formation constants deduced from the gas-phase atom recombination studies are at least an order of magnitude greater than the comparable molecular iodine-aromatic complexes in the liquid phase.<sup>10</sup> A stronger atom complex is, in fact, to be expected, as the electron affinity of the iodine atom is greater than that of the iodine molecule. Although the formation constant for the iodine atom-hexamethylbenzene complex has been shown<sup>11</sup> to be somewhat larger than that for the molecular iodine-hexamethylbenzene complex (2.7 and 1.5 l. mole<sup>-1</sup>, respectively, both at 25°, CCl<sub>4</sub> solvent), this difference is not large enough to account for the at least tenfold difference cited above and may indicate a compensating effect between the standard enthalpies and entropies of formation not present in the gas phase. In addition, however, it has recently been shown<sup>12</sup> that gas-phase molecular iodine complexes are appreciably stronger than comparable liquid-phase complexes (although the enthalpies of formation are approximately the same), the effect diminishing with increasing strength of the complex.<sup>13</sup>

Determination of the thermodynamic properties of the liquid-phase iodine atom-aromatic complexes requires the precise measurement of absorbance changes as a function of temperature and donor concentration at two wavelengths, one of which corresponds to change in molecular iodine concentration only. Accordingly, the flash spectrophotometric apparatus of this laboratory has been modified to permit the simultaneous recording of two absorbance changes as a function of

time following flash photolysis, one in the ultraviolet region (due to dissociation of iodine in the molecular iodine–aromatic complex) and the other in the visible region (resulting from the simultaneous dissociation of iodine and formation of the atom complex).

## Experimental Section

**Flash Apparatus.** The flash spectrophotometric apparatus used in this work was a modification of the unit used in previously reported experiments in this laboratory on transient charge-transfer species.<sup>8</sup> The flash lamp consisted of two parallel quartz tubes (15-mm i.d., 1.5-mm wall thickness), each approximately 15 cm long with either cup stainless steel or 5-mm tungsten rod electrodes 12 cm apart. Semicircular Pyrex manifolds at each end positioned the tubes at a distance of 8 cm from each other and provided for common gas filling of both tubes (Xe, 60–120 mm). The lamp was mounted horizontally on the optical bench in a polished cylindrical reflector, and the reaction cell was positioned midway between the two tubes.

The discharge tubes were connected in series electrically. Two ASEA Type CTUA capacitors (625 joules each) charged in parallel were discharged across the lamp, triggering being effected by a 20–35-kv pulse applied at the midpoint connection between the two tubes. The maximum capacitance voltage possible was 10 kv. However, as with flash units elsewhere,<sup>14</sup> a "saturation effect" was also encountered here; i.e., at low energies the peak light intensity is directly proportional to the electrical energy, but at higher discharge energies the peak intensity becomes roughly constant and the flash duration time (or "tailing") increases. The voltage at which this effect becomes significant apparently is a function of the design of the apparatus and was encountered here at a much lower voltage (ca. 8 kv) than on the unit described previously<sup>14</sup> (23 kv), although the energies dissipated per unit length of discharge path (33 and 42 joules/cm, respectively) are more comparable. For the relatively fast recombination reactions reported here, it was desirable to minimize flash tailing as much as possible consistent with a high peak light intensity, and therefore all measurements were made at not more than 8 kv (800 joules).

Analyzing light from the continuous light source (Osram Type XBO 450W/P xenon lamp, powered by a Sola dc constant wattage supply further stabilized by two parallel 18-v storage battery units) was partially collimated so that it passed through the reaction cell without hitting the sides and was split past the cell with a partially silvered mirror. The transmitted portion (70%) was focused on the entrance slit of a Zeiss MM12 double monochromator and detected by an EMI 9558Q photomultiplier tube; this unit involving the larger fraction of the analyzing beam was used for lower wavelength (ultraviolet) measurements. The reflected light, for measurements in the visible spectral region, was focused on the entrance slit of a Beckman DU monochromator and detected by an EMI 9558B photomultiplier. Voltage outputs developed across load resistors (variable in steps from 10 kilohms to 1 megohm) and shunting capacitors (from 0 to 600 pf) were dc-coupled through 12AU7 cathode followers to the upper and lower 2A63 amplifier plug-in units of a Tektronix Type 565 dual-beam oscilloscope. The two traces were maintained on the cathode ray screen by opposing the dc voltages from the continuous analyzing light with variable dc voltage applied at the negative inputs of the two amplifier sections. The two sweeps were simultaneously initiated by a manual trigger switch, and the gate-out signal from the oscilloscope was used to initiate the high-voltage flash trigger pulse. The rise time of the 2A63 amplifier is 1  $\mu$ sec, and this was the limiting factor for fast time resolution. However, the time constant of each detecting assembly could be stepwise increased to a maximum of 600  $\mu$ sec by the appropriate combination of load resistor and shunting capacitor in order to give the optimum signal-to-noise ratio consistent with negligible signal distortion.

**Reaction Cell.** The Pyrex reaction cell was cylindrical (10 cm light path, 2.5 cm i.d.) with evacuated 2-cm cylindrical chambers at each end. Surrounding the cell compartment and approximately three-fourths of each end section was an annular jacket (ca. 1-cm inside thickness) through which was circulated the thermostated aqueous filter solution (1 M CuCl<sub>2</sub>·2H<sub>2</sub>O + 0.5 M CaCl<sub>2</sub>·2H<sub>2</sub>O). With this arrangement, temperature control and uniformity over the entire cell was sufficiently precise to prevent any distortion of the

analyzing light beam by density gradients at the highest temperature used.

**Purification of Materials.** To Eastman *o*-xylene was added a small amount of iodine and the solution illuminated for 36 hr. Excess iodine was removed with sodium sulfite solution; the wet *o*-xylene was shaken with portions of concentrated sulfuric acid until no discoloration of the acid occurred, washed, shaken with a 10% sodium hydroxide solution, washed, and distilled twice over sodium through a 48-cm Vigreux column, the second distillation being at a high reflux ratio. A similar procedure was used for carbon tetrachloride (Fisher reagent grade), except that chlorine was added instead of iodine before illumination, and distillation was performed over phosphorus pentoxide instead of sodium. Iodine (Fisher) was freshly resublimed and used without further purification.

**Calculations.** At  $\lambda_1$ , where it is assumed that the changes in absorbance (optical path length  $d$ ) are due only to changes in total molecular iodine concentration,  $\Delta[I_2]$  (either free or complexed)

$$\Delta A_{\lambda_1} = \epsilon_{I_2, \lambda_1} d \Delta[I_2] \quad (6)$$

(Values for the apparent molar extinction coefficient of iodine,  $\epsilon_{I_2, \lambda_1}$ , were determined at the temperatures and donor molecule concentrations used in this work in independent measurements with a thermostated Beckman DU spectrophotometer using 1-cm quartz absorption cells.) At  $\lambda_2$ , the other wavelength at which absorbance changes as a function of time are simultaneously measured

$$\Delta A_{\lambda_2} = \epsilon_{C, \lambda_2} d[C] + \epsilon_{I_2, \lambda_2} d \Delta[I_2] \quad (7)$$

where  $[C]$  is the concentration of the iodine atom–aromatic complex, and  $\epsilon_{C, \lambda_2}$  and  $\epsilon_{I_2, \lambda_2}$  are the molar extinction coefficients at  $\lambda_2$  of the complex and molecular iodine, respectively. The formation constant  $K_x$  of the 1:1 complex between an iodine atom and the donor aromatic molecule (mole fraction  $X_D$ ) is

$$K_x = \frac{[C]}{X_D[I]} = \frac{[C]}{X_D(-2\Delta[I_2] - [C])} \quad (8)$$

Rearrangement of eq 6, 7, and 8 leads to an equation similar to the well-known Benesi–Hildebrand equation<sup>15</sup> in the form suitable in particular to relatively weak complexes<sup>16</sup>

$$-\frac{2R_A}{(1 - R_A R_e)\epsilon_{I_2, \lambda_1}} = \frac{1}{\epsilon_{C, \lambda_2} K_x X_D} + \frac{1}{\epsilon_{C, \lambda_2}} \quad (9)$$

where  $R_A = \Delta A_{\lambda_1}/\Delta A_{\lambda_2}$  and  $R_e = \epsilon_{I_2, \lambda_2}/\epsilon_{I_2, \lambda_1}$ .

Trotter and Hanna have recently pointed out<sup>17</sup> that solution non-ideality will lead to different values for  $\epsilon_C$  depending on the concentration units of the donor,  $D$ , although linear plots of the Benesi–Hildebrand equation still result. This will affect also the values for  $K$  determined from these plots in addition to the conversion unit factors. In this work, however, within the rather wide experimental errors, no differences were found in  $\epsilon_C$  for the different concentration scales; mole fraction units have therefore been used throughout for comparison purposes.

## Results and Discussion

**Iodine–*o*-Xylene System.** The transient absorbance changes, present 100  $\mu$ sec following initiation of the flash discharge, were measured simultaneously at 350 and 570 m $\mu$  as functions of temperature (25, 45, and 65°) and *o*-xylene mole fraction (0.082:1, CCl<sub>4</sub> solvent), but constant ( $3.9 \times 10^{-5}$  M) initial molecular iodine concentration. The choice of the former wavelength represents a compromise between maximum ultraviolet absorption by iodine in *o*-xylene (316 m $\mu$ )<sup>18</sup> and the increasing noise-to-signal ratio at lower wavelengths; the latter wavelength is the maximum of the *o*-xylene–iodine atom complex.<sup>9</sup>

The ratios of these absorbance changes are shown in Figure 1 as a function of the reciprocal of the *o*-xylene mole fraction according to eq 9, each point representing the average of at least ten oscillograms. From these plots  $\epsilon_{c,\lambda}$  and  $K_x$  were calculated from the intercepts and slopes of the best straight lines using the method of least squares. The results are given in Table I and are compared at 25° with those of the molecular iodine-*o*-xylene complex. (In practice, the data were also plotted using the technique of Rose and Drago<sup>19</sup> in order to determine experimental scattering and to verify the validity of the thermodynamic data resulting from the specific range of conditions used; no significant differences resulted using this latter technique.)

<sup>a</sup> J. A. A. Ketelaar, *J. Phys. Radium*, **15**, 197 (1954).

Since the slopes of the lines in Figure 1 can be determined more accurately than  $K_x$ , which depends on both the slope and the intercept (i.e., the extinction coefficient), the enthalpy and entropy of formation at 25° were calculated according to the integrated form of the van't Hoff equation from the reciprocals of the slopes, thereby assuming  $\epsilon_{c,\lambda}$  and  $\Delta H^\circ_x$  are independent of temperature. These thermodynamic properties are also given in Table I.

That the equilibrium constant at 25° for the atom complex is greater than that for the molecular complex is to be expected from Mulliken's treatment of charge transfer<sup>20</sup> because of the greater electron affinity of the iodine atom, leading also to the visible shift of the charge-transfer band. The correspondence between enthalpy and entropy is also quite general, the relative values for the iodine atom complex agreeing well with those for a large number of donor species with molecular iodine.<sup>21</sup> The energy of formation of the complex, ca. -4.1 kcal/mole, is essentially the same as the calculated binding energy for a gas-phase, charge-transfer complex according to Mulliken following the method of Eusuf and Laidler.<sup>2</sup> There is little question, therefore, of the charge-transfer nature of this intermediate.

The third-order, gas-phase recombination rate constant,  $k_{app}$  (defined by eq 5), for iodine atoms with *p*-xylene as the third body is approximately  $3.3 \times 10^{11}$  l.<sup>2</sup> mole<sup>-2</sup> sec<sup>-1</sup> at room temperature.<sup>4</sup> For the recombination mechanism given by eq 3 and 4,  $k_{app} = k_2(K_c)_{gas}$ , where  $(K_c)_{gas} = k_3/k_{-3}$  is the formation constant (in concentration units) for the assumed equilib-

**Figure 1.** Absorbance changes at 100  $\mu$ sec as a function of *o*-xylene mole fraction, plotted according to eq 9: O, 25°; X, 45°;  $\Delta$ , 65°.

rium between I atoms, xylene, and the charge-transfer complex. The bimolecular rate constant  $k_4$  is easily estimated since this metathetical reaction would be expected to have essentially zero activation energy and therefore should proceed at a rate proportional to collisional frequency, the specific collision number between unlike molecules being given by

$$Z_{12}' = \sigma^2 \left( \frac{8\pi kT}{\mu} \right)^{1/2} \quad (10)$$

where  $\sigma$  is the collision diameter of the I-I pair<sup>6</sup> ( $4.3 \times 10^{-8}$  cm) and  $\mu$  is the reduced mass of the I-IM pair. The major uncertainty in this calculation is the statistical factor giving the fraction of iodine atom pairs, each atom being in its ground ( $^3P_{1/2}$ ) state, that lead to a stable configuration. Porter and Smith<sup>6</sup> have used  $1/16$  since the total degeneracy of the ground-state iodine atom is 16, whereas the degeneracy of the stable singlet molecular ground state is unity. However, Eusuf and Laidler<sup>2</sup> point out that 8 of the 16 possible states from combination of two iodine atoms are attractive and can lead to combination if stabilized by collisional deactivation; the appropriate statistical factor is therefore  $1/2$ . On this basis,  $(k_4)_{calcd} = 4.8 \times 10^{10}$  l. mole<sup>-1</sup> sec<sup>-1</sup> at 25° and  $(K_c)_{gas} = 6.9$  l. mole<sup>-1</sup>. The formation constant in solution for this same intermediate species IM at 25° (Table I) is 7.4 in mole fraction units; in concentration units,  $(K_c)_{liquid} = 0.9$  l. mole<sup>-1</sup>. Agreement between the formation constants in the two phases is considered to be reasonably close in view of the experimental errors associated with the transient absorbance measurements in solution and the uncertainties in the calculation of  $k_4$ . The results do, however, indicate a smaller formation constant in the liquid phase than in the gas phase, in agreement with results for weaker complexes between atomic iodine and ethyl iodide or bromide<sup>10</sup> and between molecular iodine and benzene or diethyl ether.<sup>12</sup> This behavior is presumably due to competition between complexing and solvation of the donor molecule in the liquid phase,<sup>22</sup> the disagreement between the formation constants in the two phases decreasing with increasing strength of the complex.<sup>12</sup> (For the stronger complex between molec-

ular iodine and diethyl sulfide, the agreement between the two phases is much closer.<sup>13</sup>

The negative temperature dependence of the gas-phase recombination of iodine atoms with xylene as a third body has not been determined, but certainly is less than that for toluene ( $-3.4$  kcal/mole) and is probably close to the  $-4.1$ -kcal/mole complex formation energy obtained in this liquid-phase work. It is thus quite clear that charge-transfer interactions can account for both the third-body specificities and observed negative recombination temperature coefficients for relatively efficient third-body species.

The formation of molecular iodine in the liquid phase after the dissociation flash intensity has decayed to a negligible value is second order (as shown by linear time plots of  $1/\Delta A_{850}$ ) and is consistent with a bimolecular recombination mechanism involving free or complexed iodine atoms where a third body is essentially in contact in every bimolecular encounter. The second-order rate constant,  $k$ , defined by

$$\frac{d[I_2]}{dt} = -\frac{1}{2} \frac{d[I]_{\text{total}}}{dt} = k[I]_{\text{total}}^2 \quad (11)$$

where  $(I)_{\text{total}}$  is the total iodine atom concentration (free or complexed) was calculated from the slope of this second-order plot and eq 6 ( $[I]_{\text{total}} = -2\Delta[I_2]$ ) for each oscillogram, and the average values are summarized in Table II for each concentration at 25, 45, and 65°. At 25°, the rate of recombination is in good agreement with the rate of recombination in pure carbon tetrachloride.<sup>23</sup>

Table II. Rate of Recombination of Iodine in *o*-Xylene-Carbon Tetrachloride Solutions

#### Combination of the Smoluchowski relation

$$k = \frac{8\pi aDN}{1000} \quad (\text{l. mole}^{-1} \text{ sec}^{-1}) \quad (12)$$

which gives the diffusion-controlled recombination rate constant assuming that even on a molecular scale the solvent can be treated as a continuous medium of viscosity  $\eta$  and the Stokes-Einstein equation for the diffusion coefficient

$$D = \frac{kT}{6\pi\eta a_s} \quad (\text{cm}^2 \text{ sec}^{-1}) \quad (13)$$

shows that the product  $k\eta$  should be a function only of temperature

$$k\eta = \frac{4RTa}{3000a_s} \quad (14)$$

(23) R. L. Strong and J. E. Willard, *J. Am. Chem. Soc.*, **79**, 2098 (1957).

if the encounter diameter in solution ( $2a$ ) pertinent to the recombination process is taken to be the same as the diffusion diameter ( $2a_s$ ). The viscosities for all the *o*-xylene-carbon tetrachloride solutions used in this work were determined at 25, 45, and 65° with an Ostwald viscometer (modified at the top to prevent evaporation of the solution at the higher temperatures) which was calibrated with the two pure liquids *o*-xylene and carbon tetrachloride at 25°; these are tabulated in Table III with the densities (measured at room temperature with a Westphal balance and assumed to be independent of temperature) and values for  $k\eta$ .

Table III. Values of  $k\eta$  for Iodine Atom Recombination in *o*-Xylene-Carbon Tetrachloride Solutions

[ <i>o</i> -Xylene], mole fraction	$\rho_{25}$ , g cc <sup>-1</sup>	$\eta_{25}$ , cp	25° $k\eta \times 10^{-7}$ l. <sup>2</sup> mole <sup>-2</sup> sec <sup>-1</sup>	45°	65°
0.00	1.590	0.901			
0.082	1.508	0.886	4.7	5.0	4.4
0.167	1.430	0.875	4.7	5.1	4.1
0.255	1.360	0.860	4.6	4.2	3.6
0.446	1.216	0.831	4.3	3.7	3.7
0.651	1.080	0.803	4.4	3.9	3.4
1.00	0.880	0.753	3.4	3.0	2.3

It is seen that  $k\eta$  is, in fact, roughly constant at room temperature but decreases with increasing *o*-xylene concentration at the higher temperatures. Since two iodine atoms must come into close proximity for recombination to occur, the apparent encounter diameter ( $2a$ ) should be approximately constant (or decrease by a steric effect), whereas the average diffusion diameter ( $2a_s$ ) must surely increase with increased extent of complexing, both factors leading to the observed behavior. The net effect, however, is to give an inverse temperature relationship in  $k\eta$  at the higher *o*-xylene concentrations, approximately 90% of the iodine atoms being complexed in pure *o*-xylene. A similar effect (or constancy of  $k$ , as shown in Table II) in a pure donor has also been observed by Gover and Porter for iodine in benzene<sup>10</sup> and has been interpreted in part as a possible compensation by a temperature dependence of the extinction coefficient, since in the benzene-iodine system only the ratio  $k/\epsilon$  can be determined. The fact that there is appreciable overlapping of the molecular iodine-iodine atom-benzene complex spectra in the visible region would be expected to lead to just such an effect, but should not be a major factor in measurements made at 350 m $\mu$  on the atomic iodine-*o*-xylene complex since presumably there is negligible contribution to the absorbance at 350 m $\mu$  of the atomic complex absorption curve. At the lowest concentration, the expected constancy of  $k\eta$  is roughly followed and is consistent with the temperature coefficient for the recombination of iodine atoms in carbon tetrachloride.<sup>24</sup>

# The Crystal and Molecular Structure of the Silver Nitrate Complex of *cis,cis,cis*-1,4,7-Cyclononatriene, $C_9H_{12}(AgNO_3)_2$

Richard B. Jackson and William E. Streib<sup>1</sup>

Contribution No. 1399 from the Department of Chemistry, Indiana University, Bloomington, Indiana 47401. Received October 5, 1966

**Abstract:** The structure of the silver nitrate  $\pi$  complex of *cis,cis,cis*-1,4,7-cyclononatriene,  $C_9H_{12}(AgNO_3)_2$ , has been determined by a three-dimensional single-crystal X-ray diffraction investigation. The complex crystallizes in space group  $R\bar{3}c$ ; cell dimensions for the triply primitive hexagonal cell are  $a = 16.258$  and  $c = 9.556$  Å at approximately  $-125^\circ$ . The cyclononatriene ring is in the crown configuration and shows little or no distortion due to the complex formation. Each silver is associated with only one ethylenic bond at divergent ends of the  $\pi$ -bonded  $p$  orbitals. The silver ions are distorted  $17^\circ$  in the direction of the *cis* hydrogens.

structure of *cis,cis,cis*-1,4,7-cyclononatriene,  $H_{12}$ ,<sup>2-4</sup> is known to have a crown configura-

Silver complexes of olefins are well known<sup>5</sup>; several<sup>6-13</sup> have been investigated by X-ray diffraction techniques. The present study was undertaken to elucidate the geometry of the nine-membered system and to compare the bonding in the olefin part of its silver complex.

## Experimental Section

**Collection.** White needles of  $C_9H_{12}(AgNO_3)_2$  were prepared and supplied to us by Dr. Karl Untch. Irregular single crystals approximately  $0.2 \times 0.2 \times 0.3$  mm were cleaved and used, the first of these with the needle axis along the goniometer axis. Preliminary Weissenberg and precession photographs indicated a rhombohedrally centered hexagonal unit cell, the hexagonal axis corresponding to the needle axis. The conditions for selection,  $-h + k + l = 3n$  for  $hkl$  and  $l = 2n$  for  $h\bar{h}0l$ , indicated the space group to be  $R3c$  or  $R\bar{3}c$ . Cell dimensions obtained from film measurements and an approximate density (by weighing) of  $2.9$  g/cm<sup>3</sup> indicated six molecules in the hexagonal unit cell. It was assumed, and later verified, that the molecule has the same symmetry,  $3m-C_{3v}$ , as its parent compound. This symmetry condition restricted the space group to  $R\bar{3}c$ , since  $R3c$  would have required the molecule to have  $3C_{2v}$  or  $32-D_3$  symmetry. Data sets of three-dimensional, low-temperature intensity data were collected: initially (a) integrated Weissenberg multiple film using  $Cu K\alpha$  radiation, of levels  $hkl0-hkl3$  and  $0k\bar{l}-8k\bar{l}$ ; later refinement (b) counter-diffractometer data, collected with  $Mo K\alpha$  radiation on a General Electric spectrometer equipped with a single-crystal orienter and scintillation counter. Threefold redundant data were measured for 483 unique intensities and 364 unique counter intensities. The integrated data were measured with a Nonius Model I densitometer. Both data sets were collected at low temperature using a conventional liquid vapor cold stream in order to reduce thermal motion and to avoid a gradual surface decomposition of the crystals. Im-hexagonal cell dimensions, obtained by least-squares fit

with diffractometer  $2\theta$  data, were  $a = 16.258 \pm 0.005$  and  $c = 9.556 \pm 0.003$  Å at approximately  $-125^\circ$ .

**Computations.** All calculations were performed on a CDC 3600 computer. The raw data were correlated and corrected for Lorentz and polarization effects using a program written at this laboratory. Standard errors for the film intensities were based on observed deviations during film correlation with a minimum error of  $0.05I_{obsd}$  to avoid accidental agreement. Standard errors for the counter data were based on counting statistics as described by Johnson.<sup>14</sup> Cell dimensions and errors were determined using the least-squares program by Heaton, Gvildys, and Mueller.<sup>15</sup> Patterson and electron-density maps were computed using the Gvildys Fourier summation program.<sup>17</sup> The Busing and Levy full-matrix least-squares program<sup>18</sup> was used for the structure refinement, and their function and error program<sup>19</sup> was used for calculation of bond distances, angles, anisotropic parameters, and their respective standard deviations.

**Structure Determination.** The structure was solved by the heavy-atom method. The  $x$  and  $y$  silver atom coordinates were determined from a two-dimensional Patterson map calculated from 40  $hkl0$  film intensities. Since there was only one silver atom in the asymmetric unit and the position of the origin along the  $c$  axis was arbitrary, we proceeded directly to a three-dimensional least-squares refinement. Two cycles, varying the silver coordinates and the absolute scale factor, decreased the residual,  $R = \sum ||F_o| - |F_c|| / \sum |F_o|$ , from 0.41 to 0.22. A three-dimensional Fourier map revealed the approximate positions of the carbon ring atoms. After two least-squares cycles refining silver and carbon coordinates, another difference map was computed and the nitrate group atoms were located. Further refinement of all coordinates (except hydrogen), scale factor, and isotropic temperature factors failed to lower  $R$  below 0.185. The relatively high value of  $R$  at this stage of refinement led us to make a correction for systematic errors in the form of artificial temperature factors. The film data were collected over an extended period of time involving more than one crystal and several interruptions in the operation of the cold stream. It was therefore suspected that the various film packs may have been exposed at somewhat different temperatures and that this would constitute the major systematic error. The original intensities were corrected according to the relation  $I_{scaled} = k I_{obsd} \exp(-B_i \sin^2 \theta / \lambda^2)$ , where  $I_{obsd}$ 's are the observed intensities for a given film pack,  $k$ , is the correlation scale factor for that pack, and  $B_i$  is the individual film pack temperature factor which was fitted by least squares. Two cycles of isotropic refinement with the corrected intensities, followed by two cycles with anisotropic tempera-

observed structure factors are listed in Table I which, in addition, includes 70 unobserved intensities estimated (at the raw-data level) as half the minimum observed intensity. The unobserved data were not used in the least-squares refinements.

## Results

Atom coordinates, isotropic temperature factors, and their standard deviations are given in Table II. Interatomic distances and angles and their errors are given in Table III.

Table II. Atomic Coordinates and Isotropic Temperature Factors

Atom	$x/a_1$	$y/a_2$	$z/c$	$B, \text{\AA}^2$
Ag	0.8717 (1) <sup>a</sup>	0.2823 (1)	0.2441 <sup>b</sup>	...
C <sub>1</sub>	0.7969 (10)	0.3549 (11)	0.3657 (14)	1.08 (28)
C <sub>2</sub>	0.7306 (11)	0.2589 (11)	0.3624 (12)	1.34 (27)

O <sub>1</sub>	0.2868 (7)	0.3018 (8)	0.1806 (10)	2.03 (22)
O <sub>2</sub>	0.2928 (7)	0.1792 (7)	0.2521 (12)	1.46 (23)
O <sub>3</sub>	0.3825 (8)	0.2645 (8)	0.0805 (11)	2.56 (24)
N	0.3217 (8)	0.2483 (8)	0.1690 (11)	1.24 (22)

<sup>a</sup> Standard deviations are  $\times 10^4$  for coordinates and  $\times 10^3$  for  $B$ 's. <sup>b</sup> The position of the origin along the  $c$  axis is arbitrary and was chosen for convenience in computing a suitable unit in the electron-density maps. <sup>c</sup> See Table IV for the anisotropic thermal parameters for silver.

As proposed,<sup>14</sup> the cyclononatriene ring retains the crown configuration on complex formation with silver nitrate. The rings are stacked along the threefold axes

Figure 1. The environment of a silver ion ( $Ag_1$ ) showing all neighboring oxygen atoms.  $Ag_1$  and  $Ag_2$  are related by a threefold axis;  $Ag_1$ ,  $Ag_4$ , and  $Ag_5$  are related by a  $3_1$  screw axis. A  $3_2$  screw axis relates the  $NO_3$  groups 4–5–6, 7–8–9, and 10–11–12. Oxygens  $O_2$ ,  $O_3$ ,  $O_4$ ,  $O_5$ ,  $O_7$ ,  $O_8$ , and  $O_{12}$  are within 4.0 Å of the silver ion.  $Ag_1$ – $O_2$ ,  $Ag_1$ – $O_4$ ,  $Ag_1$ – $O_7$ , and  $Ag_1$ –(midpoint of  $C_1$ – $C_3$ ) are the shortest distances and are in a roughly tetrahedral configuration (dotted lines).

of the crystal at intervals of  $c/2$ , each ring being rotated  $35.7^\circ$  from its nearest neighbors above and below. Each silver ion interacts with only one double bond, all other double bonds directionally feasible being greater than 5 Å distant. The closest approach of any two silver ions is 4.5 Å. Several nitrate groups surround the silver ions (Figure 1); five oxygen atoms approach within 3 Å, and three of these are close enough to 2.46, the sum of the atomic radii, to suggest some degree of covalency.<sup>8</sup> These three oxygens together with the midpoint of the interacting double bond form a roughly tetrahedral arrangement around silver.

The average N–O bond length of 1.25 Å compares well with values determined in other silver nitrate complexes<sup>8,10</sup> and in  $AgNO_3$  itself.<sup>20</sup> It is slightly greater than the value of  $1.218 \pm 0.004$  Å reported<sup>21</sup> for  $NaNO_3$ . The average O–N–O bond angle is  $120^\circ$ , and the group is planar within experimental error.

The local environment of the nitrate group consists of three silver ions ( $Ag_2$ ,  $Ag_4$ , and  $Ag_5$ ) within 3.25 Å of the nitrogen atom which describe a plane somewhat above and parallel to the  $NO_3$  plane.  $Ag_3$  lies below and at a distance of 4.25 Å from the nitrogen atom. As is indicated by the Ag–O bond lengths in Table III, the silver–oxygen coordination is not simple. It appears as if each silver ion above the  $NO_3$  group interacts with two oxygens and that  $Ag_3$  is coordinated only to  $O_4$ .

Silver anisotropic temperature parameters,  $U_{ij}$ 's, are given in Table IV. Also tabulated are the direction cosines ( $\phi$ ,  $\psi$ , and  $\omega$  corresponding to the cell edges  $a_1$ ,  $a_2$ , and  $c$ , respectively) and root-mean-square displacements of the principal axes of the ellipsoid of vibration. The errors in the directions of the principal axes are large. The only general conclusion drawn is that the most extensive thermal vibration is approximately along the  $c$  axis but is tilted slightly so that principal axis  $P$

Figure 2. The cyclononatriene ring with assumed hydrogen positions. The silver ion is shown interacting with carbons  $C_1$  and  $C_2$  and distorted  $17^\circ$  from the normal position (dotted lines) along the perpendicular bisector of the ethylene group.  $P$ ,  $Q$ , and  $R$  are the principal axes of thermal motion for the silver ion. One  $\pi$ -bonded p orbital is shown in its normal position. The lower lobe is convergent with five other lobes below the ring.

(Figure 2) lies almost parallel to the plane  $C_9-C_1-C_2-C_3$ . Therefore the silver motion is perpendicular to the direction of the p orbitals and allows the silver to remain approximately equidistant from the double bond throughout the vibration.

<sup>a</sup> Anisotropic temperature factors were calculated and refined in the form  $\exp[-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}kl)]$  and were converted [D. W. J. Cruickshank, *Acta Cryst.*, **19**, 153 (1965)] to  $U_{ij}$ 's according to  $U_{11} = \beta_{11}/a^*{}^2\pi^2$ , etc.

## Discussion

The carbon ring geometry is almost identical with that of the uncomplexed *cis,cis,cis*-1,4,7-cyclononatriene.<sup>6</sup> The only possibly significant change is a stretching of the  $C_1-C_2$  bond from 1.34 to 1.38 Å which would indicate a weakening due to the silver interaction as is also indicated by infrared studies of other silver  $\pi$  complexes.<sup>22</sup> The increase in the normal trigonal angles to an average of  $124^\circ$  has the effect of separating the intraannular hydrogen atoms as discussed previously.<sup>6</sup> It would appear, therefore, that the structure of the cyclic olefin is changed little, if at all, with silver complex formation.

At the request of a referee, an attempt was made to observe the effect of the hydrogen atoms on the ring geometry. The hydrogen positions (Table V) were not apparent in the difference Fourier maps and were therefore estimated using standard criteria. Two cycles of least-squares refinement resulted in a shortening of the  $C_1-C_2$ ,  $C_2-C_3$ , and  $C_3-C_4$  bond lengths to 1.372, 1.514, and 1.536 Å, respectively. The angle  $C_2-C_3-C_4$  is

increased to  $109.4^\circ$ ,  $C_1-C_2-C_3$  to  $126.9^\circ$ , and  $C_3-C_4-C_5$  to  $123.8^\circ$ . These values generally show poorer agreement with normal bond lengths and angles than those previously obtained (Table III). Also, with the exception of the angle  $C_2-C_3-C_4$ , all shifts were within one standard deviation. Therefore the shifts were considered meaningless and Tables II-IV, which are based on the final refinement without the hydrogen atoms, were retained.

Table V. Estimated Hydrogen Coordinates

Atom	$x/a_1$	$y/a_2$	$z/c$
H <sub>1</sub>	0.859	0.383	0.434
H <sub>2</sub>	0.741	0.210	0.427
H <sub>3</sub>	0.625	0.141	0.242
H <sub>4</sub>	0.648	0.254	0.182

The Ag-C distances of 2.379 and 2.411 Å are within error of those obtained for the humulene-silver nitrate adduct,<sup>10,11</sup>  $C_{18}H_{14}(AgNO_3)_2$ , and the silver nitrate adduct of norbornadiene,<sup>12</sup>  $C_7H_8(AgNO_3)_2$ . Corresponding values for the silver nitrate adduct of cyclooctatetraene,<sup>8</sup>  $C_8H_8AgNO_3$ , and its dimer,<sup>9</sup>  $C_{16}H_{16}AgNO_3$ , are approximately 0.1 Å longer due to the interaction of two or more ethylenic bonds with each silver ion.

The slight difference in the two Ag-C distances has been observed in all the silver  $\pi$  complexes thus far studied in detail. Turner and Amma<sup>23</sup> have explained the discrepancy for silver aromatic complexes in terms of molecular orbital theory. The 5s orbital of silver is expected to accept electrons from the bonding  $\pi$  orbital ( $e_1$ ) and the filled d orbitals to donate electrons to the antibonding  $\pi$  orbital ( $e_2$ ). The silver ion seeks a position allowing maximum overlap, which is directly above one of the carbon p lobes for the 5s, but is above and symmetrically between two carbon atoms for the d orbital. It is postulated that the equilibrium is a compromise somewhat off center, hence the difference in bond lengths. The same argument can be applied to Ag-olefin complexes although the observed discrepancy is considerably less than in Ag-aromatic complexes.

Several considerations enter a rationale for the fact that in  $C_9H_{12}(AgNO_3)_2$ , the plane  $Ag_1-C_1-C_2$  is not perpendicular to the  $C_1-C_2-C_3-C_4$  plane but rather forms an angle of  $107^\circ$  with it (Figure 2). This distortion of  $17^\circ$  from the normal silver position which would assure maximum overlap with the  $\pi$  orbital can be explained by (a) steric repulsions between the silver ion and the intraannular hydrogens or carbon atoms  $C_3$  and  $C_6$ ; (b) a twisting of the  $\pi$ -bonded p orbitals themselves so that silver is, in fact, in the optimum position for overlap; or (c) homoconjugation.

That steric effects play an important role in forcing the silver ion away from the ring is unlikely since in the normal position silver is encircled by a nearly symmetrical ring of hydrogen atoms (Table VI). Carbon atoms  $C_9$  and  $C_3$  would be too far away (3.3 Å) and in unfavorable directions to exert much steric influence. Also there is no evidence of twisting of the

Ag-H <sub>4</sub>	3.49	Ag <sub>a</sub> -H <sub>4</sub>	3.04
Ag-H <sub>5</sub>	3.40	Ag <sub>a</sub> -H <sub>5</sub>	2.94
Ag-H <sub>6</sub>	3.40	Ag <sub>a</sub> -H <sub>6</sub>	3.15

<sup>a</sup> Ag<sub>a</sub> refers to silver in the normal position estimated at  $x/a_1 = 0.850$ ,  $y/a_2 = 0.289$ ,  $z/c = 0.187$ .

C<sub>3</sub> and C<sub>9</sub> atoms about the C<sub>1</sub>-C<sub>2</sub> bond. The dihedral angle between C<sub>1</sub>-C<sub>2</sub>-C<sub>3</sub> and C<sub>2</sub>-C<sub>1</sub>-C<sub>9</sub> is  $1.8 \pm 2.3^\circ$ .

That the divergent lobes of the p orbitals are twisted outward from their normal positions (assuming sp<sup>2</sup> hybridization) is consistent with the argument<sup>24</sup> that in *cis*-ethylenic systems the  $\pi$ -bonded carbon p orbitals are distorted in order to relieve strain due to bond oppositions. (It is noteworthy that for the *trans* double bond in the humulene-silver nitrate adduct the silver ion is distorted only  $5^\circ$  from the normal position, whereas for the *cis* double bonds in the norbornadiene adduct, the distortion is approximately  $24^\circ$ .)

Finally, a distortion of the p orbitals could be attributed to a rotation of the p orbitals about the C<sub>1</sub>-C<sub>2</sub>

(24) P. D. Gardner, R. L. Brandon, and N. J. Nix, *Chem. Ind. (London)*, 1363 (1958).

axis affecting a further spreading of the divergent lobes and a congestion of those which are convergent. The driving force for such a distortion would be a stabilization due to increased overlap of the convergent lobes and resulting homoconjugation. It is unlikely that homoconjugation is a very important factor in the bonding of the complex. Homoaromaticity in cyclononatriene itself is expected to be small according to simple LCAO-MO calculations,<sup>2,4</sup> and it would seem reasonable that the silver ion would tend to withdraw electrons during complex formation, thus further decreasing any existing p-orbital overlap. Also, increases in the trigonal carbon angles and a decrease in the tetrahedral angles of the ring, which would be expected to accompany significant homoconjugation, are small and can be explained by the intraannular hydrogen interactions.

## Proton and Phosphorus-31 Nuclear Magnetic Resonance Studies of Tetraalkoxyphosphonium Hexachloroantimonates and Related Compounds<sup>1a</sup>

Jack S. Cohen<sup>1b</sup>

Contribution from the Department of Isotope Research, Weizmann Institute of Science, Rehovoth, Israel. Received November 15, 1966

**Abstract:** Tetramethoxyphosphonium hexachloroantimonate (Ia) was obtained in moderate yield from the reaction between trimethyl phosphite and methyl hypochlorite in the presence of antimony pentachloride (reaction ii, X = O). Proton and phosphorus-31 nuclear magnetic resonance (nmr) and infrared and conductivity studies support this formulation. Evidence was also obtained for the formation of the triethoxymethoxy- and triphenoxy-methoxyphosphonium cations. These results confirm that such salts are intermediates in the reaction between phosphite triesters and alkyl hypochlorites. The control reaction (iii) between trimethyl phosphite and antimony pentachloride gave a minor product which was shown to be trimethoxymethylphosphonium hexachloroantimonate (II), the intermediate from intermolecular transmethylation.

Current advances in the understanding of the mechanisms of phosphorus reactions owe much to the detection and characterization of four- and five-covalent intermediates resulting from valency expansion of phosphorus(III) compounds.<sup>2-11</sup> While stable pentaalkoxy-

phosphoranes<sup>2</sup> and trialkoxyalkylphosphonium salts<sup>3,4</sup> have been isolated, the tetraalkoxyphosphonium salts have only been tentatively identified as transient intermediates. Denney and Relles<sup>12</sup> observed their formation using proton nmr in the reactions between trialkyl phosphites and neopentyl hypochlorite (reaction i).

Antimony pentafluoride and related compounds have been used extensively in the now classical work of Olah and co-workers<sup>13</sup> for the isolation of salts of relatively unstable carbonium ions. Hilgetag and Teichmann<sup>14</sup> applied this technique to the reaction between trialkyl phosphites and alkyl sulfonyl chlorides (reaction ii, X = S) to give isolable tetraalkoxythiophosphonium salts (I, X = S). The present work describes a similar application of the technique to the trialkyl phosphite-alkyl hypochlorite reaction (ii, X = O) leading to the first isolation and characterization of a tetraalkoxyphosphonium salt (Ia).

Investigation of the control reaction (iii) between trimethyl phosphite and antimony pentachloride led to the isolation of the minor product trimethoxymethylphosphonium hexachloroantimonate (II),<sup>15</sup> which was shown to be the intermediate for intermolecular transmethylation.

## Experimental Section

All phosphites were distilled and stored in a desiccator (sodium drying is not recommended). Antimony pentachloride (90%) was obtained from the Baker and Adamson Co., Morristown, N. J. The methylene dichloride used was analytical grade and was dried over calcium chloride. All melting points are corrected.

**Nuclear Magnetic Resonance Spectroscopy.** Proton nmr data were obtained using a Varian Associates A-60 spectrometer. Chemical shifts are quoted in  $\tau$  values relative to tetramethylsilane ( $\tau$  10) as external reference.

Phosphorus-31 nmr data were obtained using a Varian Associates 4300B spectrometer operating at 24.3 Mcps with 5- or 15-mm nonspinning sample tubes. Chemical shifts are quoted in  $\delta$  ppm relative to 85%  $\text{H}_3\text{PO}_4$  as external reference. Unstable materials were stored and manipulated in nmr tubes at liquid nitrogen temperature.

**Tetramethoxyphosphonium Hexachloroantimonate (Ia).** A methylene dichloride solution of methyl hypochlorite was prepared by carefully controlled (to pH 8.0) addition of 1 *N* acetic acid to sodium hypochlorite solution (4–6%, 90 ml) and methanol (2.8 ml).<sup>16</sup> The methyl hypochlorite was extracted with methylene dichloride (five 5-ml portions) until no more yellow coloration was obtained. The extracts were dried (calcium chloride) and filtered into a four-necked flask, fitted with a reflux condenser and a calcium chloride tube, and cooled to  $-70^\circ$  in an acetone–Dry Ice bath. Methylene dichloride solutions (15 ml) of trimethyl phosphite (3.5 ml, 1 mole) and antimony pentachloride (3.8 ml, 1 mole) were added dropwise under dry nitrogen with stirring. After the addition was completed (15–30 min), the flask was allowed to warm slowly up to  $10^\circ$ . Ether or petroleum ether (sodium dried) was added, and a white solid precipitated. This was separated by filtration using a sintered glass disk, washed with ether, and dried in a desiccator. Tetramethoxyphosphonium hexachloroantimonate (Ia) was recrystallized three times from methylene dichloride–ether and had mp  $139^\circ$  dec; 5.6 g (38%).

Anal. Calcd for  $\text{C}_4\text{H}_{12}\text{O}_5\text{Cl}_6\text{PSb}$ : P, 6.3; Cl, 43.5. Found: P, 6.5; Cl, 43.6.

(16) M. Anbar and I. Dostrovsky, *J. Chem. Soc.*, 1094, 1105 (1954).

The solid slowly decomposed during several weeks in an evacuated desiccator.

**Proton Nmr Studies on Ia.** (i) The solutions of methyl hypochlorite extracted into methylene dichloride and deuteriochloroform solvents showed only one product peak,  $\tau$  6.02, in the proton nmr spectrum.

(ii) The spectrum of the crude product Ia in methylene dichloride solution contained only a doublet centered at  $\tau$  5.70 ( $J_{\text{PH}} = 11.2$  cps). Impurities were less than 5%. To a solution of a recrystallized sample of Ia at  $-50^\circ$  a solution of trimethyl phosphite (10%) in methylene dichloride was added dropwise. An exothermic reaction ensued, and the nmr spectrum of the solution now contained ten major peaks including a doublet at  $\tau$  8.5 ( $J_{\text{PH}} = 17$  cps).

(iii) There was no change in the spectrum of a solution of Ia in methylene dichloride after standing at  $23^\circ$  for 24 hr. On heating at  $50^\circ$  for 2 hr, the following doublets were observed:  $\tau$  5.80, 5.85, and 7.82 (the latter two in a ratio of 3–3.5:1) with coupling constants  $J_{\text{PH}}$  of 11.5, 11.5, and 17.2 cps, respectively. Ia was almost insoluble in  $\text{CHCl}_3$  and  $\text{CDCl}_3$ .

**Infrared Studies on Ia.** An infrared absorption spectrum was recorded using a Beckman IR-7 spectrophotometer on a 4% methylene dichloride solution of Ia in a 0.5-mm cell. The bands shown in Table I were observed.

Table I

Band, $\text{cm}^{-1}$	Assignment
874 (m)	Sym P—(OC) <sub>4</sub> stretching
1088 (s)	Asym P—(OC) <sub>4</sub> stretching
1189 (m)	C—OP stretching
1270 (m)	P=O stretching
1454 (w)	CH <sub>3</sub> asym bending
2310 (w)	$2 \times 1189 \text{ cm}^{-1}$
2990 (s)	CH <sub>3</sub> sym C—H stretching
3055 (vs)	CH <sub>3</sub> asym C—H stretching

A spectrum was also recorded using a Perkin-Elmer Infracord spectrophotometer on a KBr disk of Ia. This showed no band corresponding to P=O stretching. All other bands were as given in Table I.

**Conductivity Studies.** Measurements were taken on a Barnstead PM3A conductivity meter operating at 60 cycles and  $23^\circ$ . The following values were recorded for the specific conductivities of  $10^{-4}$  *M* solutions in methylene dichloride of compounds Ia and II;  $1.08 \times 10^{-6}$  and  $1.22 \times 10^{-6} \text{ ohm}^{-1} \text{ cm}^{-1}$ , respectively. Pure methanol gave a value of  $7.4 \times 10^{-7} \text{ ohm}^{-1} \text{ cm}^{-1}$ , methylene dichloride was nonconducting, and a number of tetraalkylammonium salts gave values in the range  $2.0$ – $2.3 \times 10^{-6} \text{ ohm}^{-1} \text{ cm}^{-1}$ .

**Trimethoxymethylphosphonium Hexachloroantimonate (II).** (i) Using the same conditions as described above, methylene dichloride solutions of trimethyl phosphite (1.75 ml, 1 mole) and antimony pentachloride (1.9 ml, 1 mole) were dripped into a flask containing methylene dichloride (20 ml). Addition of ether gave a white precipitate of trimethoxymethylphosphonium hexachloroantimonate, 0.8 g (12%), which on recrystallization from methylene dichloride–ether had mp  $153^\circ$  dec.

Anal. Calcd for  $\text{C}_3\text{H}_9\text{O}_5\text{Cl}_6\text{PSb}$ : Cl, 44.9. Found: Cl, 44.7.

The proton nmr spectrum in methylene dichloride solution showed two doublets centered at  $\tau$  5.87 ( $J_{\text{PH}} = 11.5$  cps) and 7.85 ( $J_{\text{PH}} = 17.2$ ).

(ii) 1,1-Dichloroethane (distilled) was used as solvent for a reaction carried out as in part i. The product (3.0 g, 21% yield) was the same as in part i; the ratio of the doublets in the nmr spectrum in methylene dichloride solution was 3:1 (1,1-dichloroethane was not a useful solvent for the product since the low-field doublet was partially covered).

**Phosphorus-31 Nmr Studies.** (i) Reactions were carried out on a small scale, using proportionately one-quarter of the amounts of the reactants given above, but with smaller volumes of methylene dichloride (2–5 ml). The reaction solutions were quickly transferred from the cooled flask into a 5-mm nmr tube and scanned in the spectrometer. Chemical shifts for the major and consistent peaks are given in Table II. The minor component at  $-56$  ppm in the control reaction (iii) could not always be observed.

(ii) A saturated methylene dichloride solution of Ia was prepared. The mean value for the chemical shift obtained, using a 15-mm

<sup>a</sup> Spectra recorded on a Varian 4300B spectrometer at 24.3 Mcps using nonspinning 5-mm sample tubes. Only major and consistent peaks are recorded. Relative peak areas were variable, values are approximate ( $\pm 1$ ). <sup>b</sup> This work. <sup>c</sup> K. Moedritzer, L. Maier, and L. C. D. Groeneweghe, *J. Chem. Eng. Data*, 7, 307 (1962). <sup>d</sup> This component not always observed. <sup>e</sup> R. A. Y. Jones and A. R. Katritzky, *Angew. Chem. Intern. Ed. Engl.*, 1, 32 (1962). <sup>f</sup> G. M. Blackburn, personal communication.

nonspinning sample tube, was -51.5 ppm. Attempts to observe the splitting pattern were unsuccessful.

(iii) Trimethyl phosphite was refluxed in methylene dichloride solution. Evolution of gas was observed. After 4 hr the solution was concentrated under vacuum, and the product showed the following chemical shifts: +3 (phosphate), -25, and -32 [(MeO) $_3$ P(O)Me] ppm in a ratio of 8:10:1 (also some residual phosphite, -140 ppm).

**Triethoxymethoxyphosphonium Hexachloroantimonate.** Methylene dichloride solutions of triethyl phosphite (5.0 ml, 1 mole) and antimony pentachloride (3.8 ml, 1 mole) were added dropwise to a solution of methyl hypochlorite. After completion of the reaction, petroleum ether (bp 30-40°) was added, and a yellow oil separated, which could not be crystallized. Some of this was pipetted into a cooled proton nmr tube and diluted with methylene dichloride. The spectrum obtained (see Figure 1) showed the following characteristics (apart from solvent peaks): multiplet centered at  $\tau$  5.32, 5.75 doublet ( $J_{FH}$  = 11.5 cps), and 8.37 distorted triplet ( $J_{HH}$  = 7 cps). An estimate of the areas under the multiplet and doublet (by weighing peaks) gave a ratio of 4:1, respectively. Heating the sample to 50 and then to 80° produced no systematic diminution in the splitting pattern of the multiplet.

**Triphenyl Phosphite-Methyl Hypochlorite Reaction.** Triphenyl phosphite (7.7 ml, 1 mole) and antimony pentachloride (3.8 ml, 1 mole) solutions were added dropwise to a solution of methyl hypochlorite in methylene dichloride. An unstable red precipitate was formed. A sample of the solution was quickly transferred to a cooled nmr tube. The spectrum showed a doublet centered at  $\tau$  5.38 ( $J_{FH}$  = 12.2 cps); an approximate ratio relative to the total broad phenyl proton multiplet was 1:10.

Addition of ether to half of the reaction mixture while still cold produced a copious brown precipitate (6 g, mp 137° dec after recrystallization of methylene dichloride-ether). The proton nmr spectrum showed a triplet at  $\tau$  8.16 ( $J_{HH}$  = 7 cps), a singlet at 5.46 (ratio 1:1.8, respectively), and a quartet at 4.98 (7 cps). Addition of ether resulted in the reprecipitation of the solid. On redissolving in methylene dichloride the nmr spectrum now showed two sets of triplets ( $\tau$  8.80, 8.20) and quartets (6.47, 5.00), as well as the singlet (4.90).

Figure 1. Section of proton nmr spectrum of triethoxymethoxyphosphonium hexachloroantimonate showing (a) multiplet of ethyl methylene protons and doublet of methoxy protons and (b) central peak of multiplet at higher resolution.

**Ethyl Ethylene Phosphite Reactions.** Ethyl ethylene phosphite was prepared by transesterification between triethyl phosphite and ethylene glycol.<sup>17</sup> A reaction was carried out as described for Ia using this phosphite but gave no useful result.

Phosphorus-31 nmr studies were carried out as described above, and the results are detailed in Table II.

**Perkow Reaction with Antimony Pentachloride.** Trimethyl phosphite (3.6 ml, 1 mole) and antimony pentachloride (3.8 ml, 1 mole) were added simultaneously to a solution of  $\alpha$ -chloroacetone (2.4 ml, 1 mole) in dichloromethane (15 ml). Addition of ether or petroleum ether to the reaction solution gave a yellow oil, the nmr spectra of which gave no consistent result.

The control reaction between  $\alpha$ -chloroacetone and antimony pentachloride in methylene dichloride solution gave a precipitate while still cold, which was filtered onto a sintered-glass disk. The proton nmr spectrum in methylene dichloride solution showed two singlets at  $\tau$  6.97 and 5.34 (ratio 3:2). On addition of aliquots of a solution of  $\alpha$ -chloroacetone in methylene dichloride, these peaks were observed to shift upfield in a stepwise manner. The solid was very unstable.

## Results and Discussion

**(a) Trimethyl Phosphite Reactions.** The simultaneous addition of trimethyl phosphite and antimony pentachloride to a solution of methyl hypochlorite<sup>18</sup> in methylene dichloride at -70° resulted in the formation of tetramethoxyphosphonium hexachloroantimonate (Ia) (38% yield). The proton nmr spectrum of this compound in methylene dichloride solution consisted of a doublet centered at  $\tau$  5.70 ( $J_{FH}$  = 11.2 cps). The value quoted by Denney and Relles<sup>12</sup> for the chemical shift of the  $\alpha$  protons of tetraepentylphosphonium chloride, with half-life at room temperature of 3 min, was  $\tau$  5.69. By comparison with trimethyl phosphite ( $\tau$  7.0), trimethyl phosphate ( $\tau$  6.5), and penta-

(17) G. M. Blackburn, J. S. Cohen, and A. R. Todd, *Tetrahedron Letters*, 2873 (1964).

methoxyphosphorus<sup>5</sup> ( $\tau$  6.3) such a value for the tetramethoxyphosphonium cation is consistent with less electron shielding at the  $\alpha$ -hydrogen atoms. The product was shown not to be a molecular complex between trimethyl phosphite and antimony pentachloride since addition of a methylene dichloride solution of trimethyl phosphate resulted in an exothermic reaction.

Comparative phosphorus-31 nmr studies were carried out on a number of reaction mixtures. Results (Table I) when trimethyl phosphite was treated with antimony pentachloride and methyl hypochlorite (reaction ii, X = O) or with antimony pentachloride alone (reaction iii) indicated the formation in the former case of an additional product with a chemical shift (relative to 85% phosphoric acid) of about -50 ppm. That this peak corresponded to the tetramethoxyphosphonium cation was confirmed by the fact that pure Ia had a mean P<sup>31</sup> chemical shift of -51.5 ( $\pm$  1) ppm in methylene dichloride solution. This value confirms the recent qualitative prediction of Ramirez and Desai<sup>2a</sup> that a tetraalkoxyphosphonium cation would have a chemical shift of the order of -60 ppm, with shielding at phosphorus intermediate between that of phosphites and phosphates.

The formation of a minor component with a chemical shift of -56 ppm in the control reaction of trimethyl phosphite with antimony pentachloride was investigated. Addition of ether to the reaction mixture resulted in the precipitation of a small amount of material. The proton nmr spectrum contained two doublets at  $\tau$  5.87 ( $J_{PH}$  = 11.5 cps) and 7.85 ( $J_{PH}$  = 17.2 cps) in a ratio of 3:1. The latter doublet corresponds reasonably well in chemical shift and coupling constant to those recorded for tetraalkylphosphonium salts.<sup>18,19</sup> Together with the chlorine analysis, this evidence indicated a formulation [(MeO)<sub>3</sub>P<sup>+</sup>Me]SbCl<sub>6</sub><sup>-</sup> (II) for the product (12% yield). While this work was in progress, the isolation of the corresponding hexafluoroantimonate was reported by Brown, *et al.*,<sup>16</sup> from the reaction between trimethyl phosphite and antimony pentafluoride. A chemical shift of -56 ppm has been assigned to a transient trialkoxyalkylphosphonium salt.<sup>2b</sup>

The trimethoxymethylphosphonium ion is the intermediate for the Arbuzov-Michaelis reaction<sup>6</sup>

Previous preparations of trialkoxyalkylphosphonium salts (as opposed to triphenoxyalkylphosphonium derivatives<sup>20</sup>) have been carried out by alkylation of phosphites with oxonium or carbonium salts.<sup>3,4</sup>

A reaction carried out in 1,1-dichloroethane solution gave the same product II in roughly the same yield, confirming that II was not in fact an Arbuzov-Michaelis intermediate derived by reaction with the solvent. This minor component is presumably an intermediate in the formation of dimethyl methylphosphonate as one of the major products of the reaction. The intermolecular reaction would account for the moderate yields of the desired tetraalkoxyphosphonium salt Ia obtained in reaction ii (*cf.* ref 14). As expected, the

peak of dimethyl methylphosphonate shows a marked relative decrease when comparing reaction ii with iii (see Table II).

Although interaction with the solvent might have been anticipated, the absence of a peak in the phosphorus-31 nmr spectrum at -18.5 ppm, the value assigned for (MeO)<sub>3</sub>P(O)CH<sub>2</sub>Cl,<sup>21</sup> appeared to show otherwise. A methylene dichloride solution of trimethyl phosphite was refluxed and then showed two major peaks at +3 (trimethyl phosphate) and -25 ppm. The latter value could only correspond to (MeO)<sub>3</sub>P(O)CH<sub>2</sub>Cl and is the same as the only hitherto unassigned value<sup>1a</sup> obtained for the reactions between trimethyl phosphite and antimony pentachloride.

The proton nmr spectrum of Ia was unchanged after standing in methylene dichloride solution for 24 hr. On heating at 50° for 2 hr doublets at the following  $\tau$  values were observed: 5.80, 5.85, and 7.82, with coupling constants  $J_{PH}$  = 11.5, 11.5, and 17.2, respectively. The latter two doublets were found to be consistently in a ratio of 3:1. It appears that the product is the same as that (II) obtained from the reaction (iii) between trimethyl phosphite and antimony pentachloride. The anticipated formation of dimethyl methylphosphonate is ruled out by the ratio of areas of the POCH<sub>3</sub> and PCH<sub>3</sub> doublets.

The infrared spectrum of Ia in solution in methylene dichloride (4%) showed some absorption at 1270 cm<sup>-1</sup>, due to P=O stretching. However, the spectrum obtained on a potassium bromide pellet of Ia had no such absorption. The infrared spectrum quoted by Hilgetag and Teichmann<sup>14</sup> for compound Ib shows a band at 583 cm<sup>-1</sup> corresponding to P-SC stretching but the apparent absence of strong absorption for P-OC stretching (at about 1000 cm<sup>-1</sup>) is surprising.

That the symmetrical P-(OCH<sub>3</sub>)<sub>4</sub> stretching of Ia absorbs as low as 874 cm<sup>-1</sup>, compared with about 970 cm<sup>-1</sup> for triethyl phosphate,<sup>22</sup> is analogous to the situation in trimethyl phosphate which shows this band at 850 cm<sup>-1</sup>.<sup>23</sup> The corresponding antisymmetrical P-(OCH<sub>3</sub>)<sub>4</sub> bands for Ia and trimethyl phosphate are at 1088 and 1042 cm<sup>-1</sup>, respectively. The C-OP stretching band at 1189 cm<sup>-1</sup> is also analogous to that of trimethyl phosphate at 1171 cm<sup>-1</sup>.

It is interesting to note that both for compound Ia and trimethyl phosphate only the antisymmetrical CH<sub>3</sub> bending gives rise to appreciable bands (at 1454 and 1447 cm<sup>-1</sup>, respectively), while the symmetrical CH<sub>3</sub> bending (which usually shows a significant band at 1380 cm<sup>-1</sup>) seems to be practically inactive. This may possibly result from the high symmetry in these cases.

The very high C-H stretching frequencies of Ia (2990 and 3055 cm<sup>-1</sup>) are not, however, shared by trimethyl phosphate, which absorbs almost normally (at 2833 and 2933 cm<sup>-1</sup>). The increase in the stretching frequency of the hydrogen atoms is unusual and might be connected with some kind of interaction between these atoms and the anionic chlorine atoms, which increases the energy needed for this stretching.

Conductivity measurements confirmed that Ia and II were salts.

(b) **Reactions with Other Phosphites.** Evidence for the formation of a new P–O bond was obtained when methyl hypochlorite was treated with triethyl phosphite and antimony pentachloride (reaction ii,  $X = O$ ,  $R = Et$ ,  $R' = Me$ ). Although no solid could be isolated in this case, addition of petroleum ether to the reaction mixture in methylene dichloride resulted in the separation of an oil. The proton nmr spectrum of this showed a doublet (Figure 1) with characteristic splitting ( $J_{PH} = 11.5$  cps) for the  $P-OCH_3$  group, and with a chemical shift ( $\tau$  5.75) expected for the presence of a positive charge at phosphorus. An additional peak was also observed at  $-50$  ppm in the phosphorus-31 nmr spectrum compared to the control reaction iii (Table I).

For the presumed product  $[(EtO)_3P^+OMe]SbCl_6^-$  it was not possible to accurately integrate the area of the doublet relative to that of the multiplet of the ethyl methylene protons (Figure 1) partly due to the fine splitting. However, an estimate of the ratio was obtained and was smaller than that required for the pure compound. Such a value would tend to indicate that no transesterification had occurred to produce, say, diethyl methyl phosphite.

The multiplet of the ethyl methylene group (Figure 1) and the distorted triplet of the ethyl methyl protons were both noted to contain a large degree of fine splitting. Some splitting in the latter case must result from the  $\gamma$ -phosphorus atom. Fine splitting has also previously been described for the methylene proton multiplet of triethyl phosphite and phosphate.<sup>24</sup> The splitting in these cases has now been found to persist in methylene dichloride solution. The observation of doubled resonances in a series of phosphate and other esters, in which the ester groupings were bulky, has been interpreted in terms of rotational isomerism.<sup>25</sup> It is possible to assign peaks in the multiplet (Figure 1) in such a way as to distinguish at least four quartets, with separations of 2 and 6 cps, as well as the splitting due to phosphorus of 8.5 cps. However, the splittings were not found to decrease on heating the sample up to  $80^\circ$ .

On treating methyl hypochlorite with triphenyl phosphite and antimony pentachloride (reaction ii,  $X = O$ ,  $R = Ph$ ,  $R' = Me$ ), a doublet was again observed in the proton nmr spectrum of the reaction solution. This corresponded in splitting ( $J_{PH} = 12.2$  cps) and chemical shift ( $\tau$  5.38) to the values expected for the presence of the  $+P-OCH_3$  group. However, it was not found possible to isolate the unstable red solid formed. Addition of ether to the reaction mixture while still cold

resulted in the formation of a stable precipitate with an nmr spectrum corresponding to the oxonium salt  $[Et_2O^+Me]SbCl_6^-$ .<sup>26</sup>

Addition of ether to the solution of this product resulted in the presence of two sets of triplets and quartets in the spectrum. This clearly indicated that the solid was not the well-known complex  $Et_2O \cdot SbCl_5$ ,<sup>27</sup> which was often formed as a side product in these reactions.

A number of reactions were repeatedly attempted using a variety of other reagents, e.g., *t*-butyl hypochlorite, but without success. The reaction of ethyl ethylene phosphite with methyl hypochlorite and antimony pentachloride and the control reaction without hypochlorite were scanned for their  $P^{31}$  nmr spectra (Table II). A peak at low field ( $-53$ ) was attributed to ethylene methylphosphonate.<sup>28</sup> The value for the intermediate cyclic tetraalkoxyphosphonium cation III would have been of interest for comparative purposes since it is a close analog of cyclic phosphate, but without  $d\pi-p\pi$  bonding.<sup>17</sup> That complete ring opening had not occurred was evidenced by the presence of a major peak ( $-18$  ppm) corresponding to the cyclic phosphate, which must be formed *via* III.

A number of unsuccessful attempts were also made to trap the phosphonium intermediate in the Perkow reaction between  $\alpha$ -chloroacetone and trimethyl phosphite using antimony pentachloride.

It is concluded that while this work represents the first isolation of a stable tetraalkoxyphosphonium salt and confirms that these compounds are intermediates in the trialkyl phosphite-alkyl hypochlorite reaction (i), the use of antimony pentachloride does not appear to provide a general technique for the scavenging of such intermediates.

**Acknowledgments.** The author thanks D. Fiat and B. Silver for help with nmr and S. Pinchas for carrying out the infrared analysis of compound Ia. G. M. Blackburn, S. Brownstein, and D. Samuel are thanked for helpful discussions. The receipt of a Postdoctoral Fellowship from the Science Research Council (U. K.) is gratefully acknowledged.

# Kinetics and Mechanism of the Inner-Sphere Electron-Exchange Reaction of Hypophosphitochromium(III) and Chromium(II) Ions in Acidic Solution<sup>1a</sup>

Kermit A. Schroeder<sup>1b</sup> and James H. Espenson

Contribution from the Institute for Atomic Research and the Department of Chemistry, Iowa State University, Ames, Iowa 50010. Received November 12, 1966

**Abstract:** The kinetics of electron exchange between  $\text{Cr}(\text{OH})_2(\text{H}_2\text{PO}_2)^{2+}$  and  $\text{Cr}^{3+}$  has been studied in aqueous acid solution. Over the range of acid concentration studied, 0.03–1.0 M, the rate equation has the form  $k[\text{CrH}_2\text{PO}_2^{2+}][\text{Cr}^{3+}]/[\text{H}^+]$ , with  $k = 6.11 \times 10^{-4} \text{ sec}^{-1}$  at 25.0° and unit ionic strength. Values of the activation parameters associated with this rate constant are  $\Delta H^\ddagger = 19.7 \pm 1.0 \text{ kcal mole}^{-1}$ , and  $\Delta S^\ddagger = -7.2 \pm 3.3 \text{ eu}$ . Ion-exchange equilibration experiments were used to confirm the net charge on the complex as +2. The reaction mechanism involves a hypophosphite bridged transition state. The probable structure of the transition state, suggested by the inverse dependence of exchange rate upon  $[\text{H}^+]$ , involves double bridging by hypophosphite and hydroxide ions. Alternative formulations are also presented.

In an acidic solution electron exchange occurs between chromium(II) and a monosubstituted chromium(III) complex  $(\text{H}_2\text{O})_5\text{CrX}^{2+}$  (eq 1). This process establishes Cr(II)–Cr(III) isotopic equilibrium, although net chem-

ical change does not occur (at least until much longer times have elapsed). Each reaction transfers  $\text{X}^-$  from Cr(III) to Cr(II) during electron exchange and the mechanism is most simply formulated as involving a transition state in which ligand X has penetrated the inner coordination sphere of both metal ions.<sup>2</sup>

The rates and mechanisms of a number of such inner-sphere Cr(II)–Cr(III) exchange reactions have been studied, including Cr(III) complexes containing fluoride,<sup>3</sup> chloride,<sup>4</sup> bromide,<sup>4</sup> thiocyanate,<sup>4</sup> and azide<sup>4,5</sup> ions. Cr(II)–Cr(III) electron exchange has been studied also in the case of two tripositive Cr(III) species,  $(\text{H}_2\text{O})_5\text{Cr}^{3+}$ <sup>6</sup> and  $(\text{H}_2\text{O})_5\text{CrNH}_2^{3+}$ .<sup>7</sup> These reactions likewise have been interpreted<sup>7</sup> in terms of an inner-sphere mechanism involving the ligand  $\text{OH}^-$ , although here only indirect evidence is available. The exchange rate law obeyed by each of these reactions takes the

form  $k[(\text{H}_2\text{O})_5\text{CrX}^{n+}][(\text{H}_2\text{O})_5\text{Cr}^{3+}]/[\text{H}^+]^n$ , with  $n = 0$  and 1. The transition states for electron exchange have a 4+ ionic charge in each case.

We report here on a study of electron exchange between chromium(II) and monohypophosphitochromium(III) ions. In earlier work,<sup>10</sup> we reported the preparation and characterization of the complex  $(\text{H}_2\text{O})_5\text{CrH}_2\text{PO}_2^{2+}$  and studied the kinetics and thermodynamics of its formation and decomposition (eq 2).

This study of electron-exchange rates was undertaken with the expectation that the exchange-rate law and mechanism would parallel the previous studies on related complexes. In addition, since phosphorus oxyanions had not been studied previously as bridging groups for Cr(II)–Cr(III) electron transfer, the hypophosphite complex appeared interesting in this respect. The role of phosphorus oxyacids in biological oxidation–reduction reactions added interest to this subject. Although we confirmed that Cr(II)–Cr(III) exchange occurs with transfer of the ligand and without observable net reaction, it soon becomes apparent to us that the reaction mechanism differed appreciably from earlier exchange systems. The observed dependence of exchange rate on  $[\text{H}^+]^{-1}$ , corresponding to a transition state of 3+ charge, constitutes a novel situation for exchange, and one that provides some information on the structure of the transition state that can be interpreted in terms of an isomeric  $\text{HP}(\text{O})(\text{OH})^-$  ligand, or in terms of a double-bridged electron-transfer mechanism.

## Experimental Section

**Reagents.** Solutions of the monohypophosphitochromium(III) complex were prepared from chromium(III) perchlorate and hypophosphorous acid as described previously.<sup>10</sup> The complex was isolated from the starting materials and from other chromium species by ion exchange. The resin column was first rinsed with 0.3 F perchloric acid to remove the free acid and any complexes of charge lower than 2+. The complex of interest was eluted with 1 F lithium perchlorate or perchloric acid. The visible and ultraviolet spectra of the complex have been reported earlier,<sup>10</sup> and spectra of all samples obtained here were in quantitative agreement with the published values. Solutions of the separated complex generally
